troublesome ; therefore the drawing of the tooth is to be preferred, because it is not so liable to this objection.¹

Before the abscess has formed, and when, as yet, it is only imminent, it may be arrested by removing any carious tooth or teeth in the neighbourhood ; and the application of leeches, fomentations, &c., with the administration of purgatives. In those cases where the pus has already accumulated, and there is no outlet, it will be necessary to make a free opening for the evacuation of the matter ; and the method, which universal experience has approved, consists in the removal of a tooth, and the perforation of the antrum at its base. This has the double advantage of removing the cause in most cases, and of allowing the discharge of the matter at the most dependent part of its containing sac. The tooth whose fangs are usually most intimately associated with the antrum is the first permanent molar ; and its removal, in a case of antral abscess, is especially indicated from this circumstance, and from the frail and perishable nature of the tooth itself, which gives it less often than other teeth a long tenure of usefulness. The relation of the fangs of the molar teeth to the antrum is an important consideration in the treatment of this disease : in the largest proportion of cases caries of the first molar is the cause, and its removal (opening an alveolus for further perforation) is the first step in the treatment ; but any other tooth, molar, bicuspid, or even canine, whose disease should be considered its cause, ought in preference to be extracted, as the absorption around the fang of a carious tooth would render the perforation of the antrum easy, while, by such a selection, this preliminary step would remove the exciting cause of the disease. Indeed, as a rule, it is well to extract all carious teeth from the side of the upper jaw affected with antral abscess. The extraction of the abscess causing tooth is frequently followed by discharge of the contained pus, in consequence of the fang having extended into the antrum, or the floor of the sinus having been absorbed, resulting from the diseased tooth. It is generally necessary to enlarge the orifice into the antrum ; and this is best effected by a naked trocar pushed up the socket of the extracted tooth : the trocar should be large, so as to break down a good deal of the floor of the antrum, thus making a free orifice for the discharge of matter. The absorption of bone which occurs around the fangs of carious teeth much facilitates piercing the antrum in this manner. Perforating the antrum occasionally requires considerable force ; and it is necessary to apply this force with great care : the forefinger should be extended on the shaft of the trocar as a guard, and the instrument should be pressed forwards with an even rotating motion. If these precautions are not taken, the floor of the antrum will sometimes give way suddenly, the trocar will traverse the cavity of the sinus, and strike hard against the floor of the orbit, which it may even pierce. I once saw this accident occur in the hands of a young operator, fortunately without any serious consequences. Mr. Coleman has devised a trocar with a guard three-fourths of an inch from the point to prevent such an accident by stopping the intrusion of the instrument further.² Occasionally antral abscess is associated with necrosis of some portion of the walls of the sinus ; and if this should occur near its floor, the removal of the dead bone will supply an available orifice for the discharge of matter and the employment of injections. The presence of necrosed bone gives to the discharge the peculiar characteristic odour which is familiar to every surgeon : the offensive smell which the pus has, when simply long pent up, is a putridity of staleness, and quite distinct from the dead-bone factor. It may not be always easy to remove dead bone at once ; and, in such a case, an outlet may be made in its neighbourhood, which will allow the discharge of the matter, and assist in the coming away of the sequestrum when it is detached. If a case were to occur in which the teeth had been long removed, and the alveolar processes absorbed, the floor of the antrum would be more difficult to pierce, on account of the thick compact layer of bone which is constituted by the *osteal cicatrix* after the removal of the

¹ *Practical Treatise on the Diseases of the Teeth*, by John Hunter, pp. 45, 46. 4to. London, 1771.

² *Manual of Dental Surgery*, by A. Coleman, F.R.C.S., p. 326.

teeth. In such a case it would be more easy to enter the antrum by perforating at the base of the malar process of the maxillary bone over the region formerly occupied by the second or third molar tooth. The mucous membrane should be divided first; and then the bone, when quite exposed, perforated by means of any instrument suitable for the purpose: a large trocar; or, as Sir B. Brodie suggests, a strong pair of scissors, closed and held firmly in the hand, should be *bored* into the part chosen for perforation.

When the antrum has been perforated, the next step is to secure the complete washing out of the cavity by injections, and the free and continued egress of the discharge by the artificial opening. Warm water should be abundantly used at first, so as to remove all the matter, which is sometimes inspissated. This will give great relief, and the swelling and inflammation will usually subside at once. Should the tendency to pus-secretion continue, an injection of sulphate of zinc, or what in an obstinate case I found very efficacious, a solution (gr. ij. to the ounce) of nitrate of silver in distilled water, may be employed. I am in the habit of using a glass syringe with an ivory nozzle; fitted to the extremity of this is a bent silver tube. In using this apparatus, the silver tube is introduced into the opening in the antrum, and kept there while the syringe is filled and used; and withdrawn, refilled, and used again, many times. When the washing out of the antrum is completed, both the syringe and the silver tube are withdrawn; and now, unless some means are taken to prevent it, accidents of two kinds may occur;—first, food may pass through the orifice into the maxillary sinus; and secondly, the aperture, thus artificially made, may close and cicatrise over. To prevent this, the plan usually adopted has been, to plug the orifice with a piece of wood, which effectually prevents both ill consequences. This is, however, a clumsy method: the same and further advantages may be gained by adopting a plan which I have followed in some recent cases. After the perforation through the alveolar cavity has been made, I have taken a model, and a plate has been prepared to pass over the space occupied by the extracted tooth, and fastened to the contiguous teeth by the customary metallic bands. Through this plate a hole has been bored, which corresponds to the orifice into the antrum; and to the applied surface of the plate a very short tube has been soldered, sufficiently long just to enter the antrum, to occupy the perforation, and prevent its closure. This plate has been permanently fixed during the active treatment of the case, and the orifice in the tube has been kept closed by a plug of cork in the intervals between using the injection. By the removal of the cork, the nozzle of the syringe, which fitted the tube, could be applied, and the injection used any number of times, the tube being sufficiently short to allow the complete washing out of the cavity and the escape of the fluid. This plan of treatment has the additional advantage, that when there is no further need of keeping open the artificial orifice, the plate over the gum facilitates its closure. By removing the tube, and closing the hole by a little sheet of metal soldered on, the passage of air and fluid from the mouth to the antrum is suspended, and the healing of the wound is thereby facilitated, as will be hereafter explained. (See section on the ‘Application of Obturators,’ &c.)

If in operations for antral abscess any foreign body, which may have caused or be associated with it, such as the fang of a tooth, becomes loose in the sinus, it should be remembered that the cavity is occasionally divided, as shown by M. Giralde¹, by partial septa of bone projecting from its walls. In such an instance, the adventitious body may be pocketed in a circumscribed region of the sinus,² and can only be removed by some curved scooping instrument introduced into the antrum; and this septate condition, too, would materially interfere with the cleansing of the cavity by means of injections.

VII. *Dentigerous cysts*.—Dentigerous cysts are collections of serum, or some modification of serum, occurring in the maxillary bones, associated with and de-

¹ *Des Maladies du Sinus maxillaire*, par M. Giralde. Paris, 1851.

² An interesting example of this casualty is mentioned by Mr. Catlin, in the *Transactions of the Odontological Society*, vol. ii. p. 38. London, 1861.

pendent upon impacted misplaced teeth.¹ These serous cysts may result from the presence of a supernumerary tooth or teeth; but in every case recorded, and in all except one that have come within my knowledge, the tooth or teeth have been normal in their presence and serial character, though misplaced as regards position: further, in every recorded case, the tooth or teeth thus implicated in disease, have been of the successional or permanent set, though a solitary instance has happened in the practice of a friend of the author's, in which a temporary tooth was the dental element of one of these cysts. These tooth-bearing serous tumours are, therefore, to be looked upon only as the occasional complications of dentition, in which there is an accidental deviation in the anatomical position of some tooth or teeth. The cysts only arise when the tooth or teeth associated with them are embedded in the substance of the jaw-bone; they do not occur after the tooth has pierced the gum. The embedding of a tooth in the bone does not necessarily give rise to these serous collections, for that is by no means an uncommon occurrence, whereas dentigerous cysts are rare. There appear to be three circumstances which may either of them produce impaction of a tooth in the substance of the maxillary bones: the tooth may be originally developed too deep in the body of the jaw and thus, though it grow in a right direction and in a right position as regards the series, it will never reach the alveolar margin; or, while it may be sufficiently superficial, it takes an oblique direction of growth, so that it lies covered more or less in the axis of the bone; or, again, the position of the tooth and its line of growth may be originally normal, but from an arrest of the development of the fang it may fail to reach the alveolar edge, and so remain permanently impacted in the maxilla.² This may occur to any tooth, and has been recorded as affecting most of the permanent set, but it is more common with some than with others: it has been more often met with as regards the upper permanent canines than any other teeth. In cases where a successional tooth is unimpacted in the jaw, its temporary predecessor is usually retained considerably after the natural period of shedding. When a tooth is thus situated, its fang is enclosed in a bony socket lined by periosteum, as in ordinary circumstances, while the crown of the tooth is free in a little bony locus lined by that which was the so called 'enamel pulp.' This structure is clothed with a sort of epithelium, which is apt to assume the function of secreting fluid. After the enamel is completely formed, the soft membrane which rests upon the surface of the crown of the tooth frequently separates from it, the interval being occupied by a sort of serum. This is

The dentigerous cysts, to which I have above referred, are totally distinct in their origin and physiological meaning from those other tooth-bearing tumours which are found, some in the ovaries of females, and others variously distributed in the bodies of either sex. The dentigerous cysts occurring in the jaw are merely the result of misplacement of a tooth, or tooth-germ belonging to the jaw which contains them. The two other forms of dentigerous cyst neither belong to the individual in whom they are found, nor are they adventitious growths of disease, properly so called. They obviously represent a portion (more or less) of another individual, and indicate some curious aberration of the function of reproduction. The ovarian tumours which bear teeth, and many fetal structures found in the ovary of the human female, I conceive to be the absolute equivalents of the virgin-produced 'zooids' of those invertebrata which perfect the function of *parthenogenesis* in the reproduction of their kind: that the development of these so-called tumours is the physiological equivalent of this function, though the anatomical result is incomplete. (See 'Ovarian Tumour containing Teeth,' &c., by the author, in *Guy's Hospital Reports*, 3rd series, vol. vi.) Those other tooth-bearing tumours which are found in various parts of the body, irrespective of sex, cannot be susceptible of the same explanation, but suggest the entanglement of an imperfect, or more or less perfect, ovum within the primary one. Teeth appear to be the most constant of the structures entering into the formation of these tumours; but they are associated with other tissues, even in more than one instance to the production of an entire foetus. These developments receive a probable elucidation by those curious monstrosities occasionally noticed in the ova of birds, in which a small imperfect egg is found within a larger primary one—not the common monstrosity of twin yolks in one egg, but a distinct miniature egg within the larger. (See Retzius, in *Oefversigt af Kongl. Vetenskaps-Akademiens Förhandlingar*, Stockholm, 1847; Baron de Morogues, in *Revue de Zoologie*, 2^e série, tome v. Paris, 1853.) Such a circumstance occurring in the human ovum may explain the presence of these dentigerous and many-tissued cysts enclosed within the body.

¹ 'On the Impaction of permanent Teeth in the substance of the Maxillary Bones,' by S. J. A. Salter, in *Guy's Hosp. Rep.* vol. v. 3rd series.

generally the result of some irritation or difficulty in tooth-cutting; and where the irritation runs on to acute inflammation, as in some cases of tedious eruption of wisdom-teeth, the secretion may become purulent. In the deep-seated cases of impaction of teeth, the action is, I believe, always slow, and the secretion almost always serous.

The recorded instances of this condition are so few, that it is scarcely possible to generalise upon them: it may, however, be said that they have usually happened in young persons, at least have commenced in adolescence, shortly after, though sometimes before, the maturation of the impacted tooth. In the cases narrated, the upper grinders have been more frequently involved than other teeth, the serous cysts dilating into the maxillary sinus: but incisors, canines, premolars, and molars, have all been associated with this condition.

M. Jourdain¹ describes three cases of dentigerous cysts. The first case he records was that of a girl, seventeen years old, in whom the right upper first and second permanent molars were inverted, and a large serous cyst had expanded around them into the antrum, with great dilatation of the body of the bone, distortion of the side of the face, and closure of the nostril: it had existed 'some months.' In a second example, a man about sixty years of age suffered from a tumour the size of a pigeon's egg in his upper jaw, for many months, closing the nostril of that side; it was caused by the expansion of a cyst around the second premolar, which was impacted deep in the substance of the bone. The third instance occurred in a girl, thirteen years of age, from a monstrous permanent lateral incisor (side not stated) being embedded in the intermaxillary bone, above and behind the root of the central incisor; 'there was a considerable tumour, which occupied anteriorly the whole region of the maxillary hollow.' It had existed for a year.

Dupuytren² describes a specimen shown to him by M. Loir, in which a cyst was developed in the left superior maxilla: this cyst involved, and was dependent upon, the presence of the canine tooth in a reversed position.

I was informed of a case of this disease by my late colleague, Mr. Bransby Cooper, in which great swelling occurred in the substance of the superior maxilla of a young man, in whose mouth the first and second permanent molar teeth had never made their appearance. A free opening was cut into the expansion, when the wanting teeth were found inverted in the axis of a serous cyst expanding into the antrum. No account of this case appears in Mr. B. Cooper's 'Lectures on Surgery,' but I took memoranda of its particulars when communicated to him.

Mr. Wormald operated on a boy, about fourteen years of age, some time since, at St. Bartholomew's Hospital, in whom a serous cyst had expanded about the second bicuspid tooth of the lower jaw; the cyst was the size of a large chestnut, and was in the axis of the bone: the fang of the tooth was not fully developed. The interior of the cyst was lined with a thick vascular membrane, and it contained a glairy fluid. Mr. Wormald has favoured me with these particulars.

F. E. Glaswald published a very learned discourse on this malady, at the University of Greifswald, in 1844, containing a complete résumé of the literature of the subject.³ The text, upon which this essay was elaborated, was a case that had been under the care and treatment of Prof. Baum. In this instance a cyst had dilated each antrum to an enormous extent, and with hideous disfigurement of feature. The patient was a woman, thirty-eight years of age, and the disease was said to have been in progressive existence for thirty years. From a cyst in the right antrum a canine tooth was removed, and from the left a molar. The fluid in the cysts was purulent.

Three instances of this condition have occurred in my own practice. In one a serous cyst expanded the left angle of the lower jaw in a young man twenty-two years of age, resulting from the impaction of the dens sapientiæ. The cyst was very large, and had been twice opened to allow the escape of serum, which had in each

² *Leçons orales de Clinique chirurg.*, Dupuytren, tome iii. p. 8. Paris, 1833.

³ *De Tumore quodam utriusque Antri Hygromi perversa dentium formatione exorto*, auctor Franciscus Edwardus Glaswald; Gryphæ, 1844.

instance rapidly re-collected. I extracted the second molar, which was loose: this ruptured the cyst, liberated the serum, and freed the impacted tooth; its crown appeared in the alveolus of the second molar, whose posterior fang was greatly absorbed by the progress of the cyst. The case was entirely cured by this means alone; and the dens sapientie gradually rose into the mouth in an oblique position. The second example is very interesting in a diagnostic point of view. A girl, eighteen years of age, had an elastic fluid-containing tumour in the substance of the incisive bone, extending up to the base of the nose on the left side. She had been seen by two or three surgeons; but the nature of the malady was not ascertained. She had the normal number of teeth in the jaw, though the *character* of one of them was abnormal for her age. When the patient was sent to me for my opinion, I perceived that the left central incisor was a *temporary* tooth; and this circumstance was a key to a correct diagnosis of the case. The left temporary central incisor occupied a position which its permanent successor should have held: the absence of the tooth, under such circumstances, suggested the almost inevitable position which it must occupy above and behind its temporary predecessor, that is in the axis of the serous cyst. The temporary tooth was removed, and the cyst explored, to discover the succeeding tooth. The permanent central incisor was found deep in the bone, in an upright and natural direction; its crown bare within the cyst; but upon its removal it was observed that the fang was aborted, and had only grown to one-fifth its natural length. This circumstance it was which had prevented its extruding its temporary predecessor, and establishing itself in its normal position. The retention of the tooth in its epithelioid sac furnished the anatomical grounds from which, under favouring circumstances of irritation, the serous secretion arose, and the bone-expansion followed. The third case was that of a gentleman about forty years of age. A cyst, the size of a pigeon's egg, had expanded around the second bicuspid on the left side, the tooth being impacted in the jaw. The fluid in the sac was thick, very dark yellow-coloured serum, containing a large quantity of cholesterine plates.

Pathological specimens of uncommon diseases, and those too not killing or shortening life, must necessarily be very rare. This applies to specimens illustrative of the disease we are considering. One is in the possession of Mr. Samuel Cartwright, jun., and is valuable and instructive in many points.¹ The preparation consists of a right superior maxilla—an adult bone: the teeth that remain, and the alveoli from which others have been extracted, show that the normal number of permanent teeth had developed in their natural position. The turbinated bones are gone, and the antrum maxillare is open. In the antrum, starting from its base, but not attached to its lateral walls anywhere, is an exceedingly thin, delicate capsule of bone, about the size of a chestnut, white with a granulated surface. The bony capsule contains nothing but one small *supernumerary* tooth, which is *loose* and *free* in the cavity. There are three important points in this specimen bearing on the anatomy and history of these cases: the tooth is a *supernumerary* one; it is free and wholly detached in the cavity of the cyst; and further, the expansion is not that of the antral wall itself, with the tooth's crown uncovered within it, but a distension of that which was the bony locus of the contained tooth, which, by its further dilatation, would have expanded the antral wall, and probably have been confounded with it.

This latter circumstance appears to me to be of much anatomical interest in reference to those serous expansions of the antrum which are associated with inverted teeth. These have hitherto been described as cysts of the antrum itself: but I cannot conceive that a tooth being 'cut' through the mucous membrane of the antrum should produce such a result. The appearance of the crown of an inverted tooth in the nostril neither causes irritation nor increased secretion—at least no such consequence followed the three examples I have seen; and it seems to me to be far more probable that these cases have commenced as cysts within the bone at the base of the maxillary sinus, expanding into it, and ultimately filling its whole cavity and dilating its walls.

¹ Through the kindness of my friend Mr. Cartwright, I have been allowed to figure this specimen. See *Guy's Hosp. Rep.* 3rd ser. vol. v. p. 328.

Two specimens in the Museum at St. Bartholomew's Hospital throw some further light on the pathology of this condition. One preparation (numbered i. 119) exhibits a thin bony cyst, the size of a small Tangerine orange, with a thick membranous lining: it contained an inferior permanent canine tooth, *loosely attached* to its walls. It was removed from the lower jaw in the region of the contained tooth. The other preparation (i. 119a) is the superior maxilla of a young sheep, in which the central incisor is attached to the side of a large cyst; the *fang* of the tooth being *almost wholly destitute of bony covering*. This denudation of the fang does not appear to exist in the early stages of these cases, but seems to be brought about by great expansion of the cyst, and the progressive absorption of bone which accompanies it.

In one instance only am I aware of a dentigerous cyst being associated with a *temporary* tooth. It occurred in the practice of my late friend Mr. Alexander Edwards of Edinburgh. The patient was a young man, in whose upper jaw, just ~~below~~ the orbit, a tumour had developed: the tumour consisted of exostosis from the maxilla, combined with a bony cyst, containing a tooth, which was pronounced by Prof. Goodsir to be a temporary molar: from a portion of the tooth, which I afterwards saw, it appeared to be the second, the larger of the two.¹

The *symptoms* of a dentigerous cyst are almost wholly local, consisting of a general expansion of the jaw-bone at some particular spot; accompanied by a corresponding disfigurement of the neighbouring features, and a sense of weight and tension at the affected part. Where the impacted tooth has produced pressure upon a neighbour, the symptoms of pain and local distress have been more considerable, and have given rise to some constitutional irritation.

Upon manipulation the fingers readily perceive that the tumour is a central expansion of bone, and that it contains fluid; the bony walls yield to pressure, and then return to shape with that peculiar kind of crepitation which Jourdain characteristically calls *craquement*, like the doubling of stiff parchment; and the bone is usually sufficiently thin at some part to allow the production of fluctuation under the pressure of alternate fingers.

One of the most usual symptoms, and which is also an important *diagnostic sign*, is the absence from the mouth of some tooth or teeth which should have appeared, and have never been extracted. The presence of a fluid-containing tumour within the substance of a maxillary bone at the region of a tooth which is missing, and known always to have been wanting, would be well-nigh conclusive as to its being a dentigerous cyst, though the presence (or the past-known presence) of every mature tooth would not necessarily prove the reverse; for the dental element in the case may be a temporary or a supernumerary tooth. However, an impacted temporary tooth is a very great rarity, and one producing a serous cyst still more uncommon: the same may be said of a supernumerary tooth. The diagnosis may be further advanced by exploring the cyst either by means of a grooved needle or trocar, when a serous discharge would support the idea of a tooth-cyst; and if the cavity be laid open, a probe will scarcely fail to discover the hard unyielding substance of the crown of the tooth.

The *treatment* of these cases is obvious, and usually quite efficacious. It consists in evacuating the contents of the cyst, extracting the tooth or teeth embedded in it, and where the expansion is large, in removing some of the dilated bone. The operations should be performed as early as possible, so as to prevent the necessity of cutting away much bone, and the prolonged and tedious absorption which would

¹ Other examples of dentigerous cysts may be referred to: - 'Tumour of the Upper Jaw depending on Cyst connected with the Presence of Teeth in a Preternatural Situation,' by James Syme, Esq., in *Edin. Med. and Surg. Journal*, vol. v. p. 381. Edinburgh, 1838. 'Tumour formed by the Capsule of an uncut permanent Tooth,' by T. Wormald, Esq., *Lancet*, vol. i. p. 750, 1850. 'Dentigerous Cysts,' in Stanley's *Diseases of the Bones*, pl. xviii. p. 20 of Illustrations; London, 1849. 'Three cases of Dentigerous Cysts,' in Forget's *Des Anomalies dentaires*, &c., Obs. x., xi., xii., pp. 41-47; Paris, 1850. 'Case of Bony Dentigerous Cyst of the Lower Jaw,' by S. W. Fearn, in *Brit. Med. Journal*, No. 101, p. 241. 1864. Heath's *Injuries and Diseases of the Jaw*, p. 158; London, 1808.

follow before the face or jaw assumes its natural form. All cutting should, if possible, be done within the mouth. Generally a portion of the wall of the cyst may be removed readily enough with a scalpel; but where the involved tooth is reversed, the expansion is likely to be away from the alveolar border. In that case bone-nippers, the extraction of contiguous teeth, or even the saw, may be necessary. This has been especially the case where inverted teeth have caused cysts in the antrum. The tooth is likely to be found at the base of the cyst, further, *i.e.* from its thinnest expansion. Some difficulty may be found in getting hold of and removing the embedded tooth; but various long-bladed extracting forceps may be readily devised to suit any case if a difficulty should arise.

In some cases, from a persistence of the serous secretion, it has been found necessary to inject the cyst with astringent and stimulating injections.

The issue of these cases is, I believe, always satisfactory. I am not aware that it ever led to necrosis or other bone-disease. In one instance which I saw, a fibrous tumour grew from the cicatrix of the wound some months after the first operation; this was removed, and did not recur.

VIII. Alveolar and maxillary necrosis from (a) *Phosphorus fumes*, (b) *Eruptive fevers*.

The relation of the phosphorus poison to the disease in question, and its method of introduction, or rather application, are among the most distinctly proved of any of the circumstances connected with the history of disease. Probably there is nothing in pathological history where clear data, and simple induction from those data, have more lucidly illustrated the questions of cause and effect. To bring about the 'phosphorus disease,' phosphorus in some form must be applied to the periosteum, or, what is equivalent to the periosteum, to some raw vascular surface in immediate connection with the nutrition of bone; and the application must be prolonged, must be under particular circumstances of temperature, and probably of oxidation. These conditions alone occur in those manufactories where phosphorus is employed in the making of lucifer-matches; and there alone (or scarcely with exception) it is that this disease is manifested. But the circumstances which connect the outward cause with the disease that follows it, is a predisposition in the individual, consisting of some exposure of the periosteum, or what is tantamount to such exposure. The only manner in which this occurs, at least in which phosphorus appears to be effective in causing bone-necrosis, is where caries of a tooth exposes the pulp to the poison-influence, the bone-necrosis being that of the jaw. It is the poisoning of the tooth-pulp that is the essence of the disease; the severe combinations of bone-affection, which give all the importance to the malady, are but contingent and secondary consequences. It is this fact in the essential nature of the disease that links it (as I think) to that other form of maxillary necrosis which occurs in children after attacks of the eruptive fevers; only that, whereas in the phosphorus disease the poison is applied to the tooth from an extraneous source—from without—in the jaw-necrosis of eruptive fevers the poison is generated within, and alights upon the teeth and tooth-pulps, by virtue of their being dermal organs, members of the tegumentary system, upon which system generally the eruptive fever-poisons spend their chief destructive force.

Phosphorus disease.—The necrosis and exfoliation of portions of the jaw-bones, dependent on phosphorus fumes as its cause, is so entirely associated with the manufacture of lucifer-matches, made with common phosphorus, that not only are all the particulars we know of the malady derived from the victims of that occupation, but the disease itself was not known to have an existence until some years after these light-producing agents had taken the place of the old tinder-box, and by the large demand for them had given rise to extensive laboratories for their production.

The earliest published account of the disease which we have is by Lorinser,¹ of

¹ have had no opportunity of consulting Lorinser's original writings: they are referred to by Geist, as—'in den medicinischen Jahrbuchern des k.k. Oesterreichischen Staates, Jahrgang 1845, Märzheft.'

the 'Bezirks-Krankenhaus, Wieden;' and the first case which fell under his notice occurred in 1839, about eleven years after the opening of lucifer-match manufactories in Vienna. In this country, as far as I am aware, the malady was first recorded by Dr. Wilks, in 'Surgical Reports of Guy's Hospital,' from April 1846 to March 1847, where he remarks: 'Of the other diseases of the lower jaw, one occurred in a lucifer-match maker, with suppuration and exfoliation of bone.'¹ It is, however, to the Continental surgeons, and those principally of Germany, that we are indebted for the complete and early account of this malady, from which all subsequent notices have been mainly derived. Besides the original memoir by Lorinser, before referred to, important contributions have been added by Strohl,² Heyfelder,³ Roussel⁴ and Gendrin, Sédillot,⁵ Ebel,⁶ and, above all, by Von Bibra and Geist,⁷ whose exhaustive treatise, their joint production, has given the clearest elucidation of this new disease.

The most important article on this subject that has appeared in this country has been written by Dr. Bristowe in the form of a Report to the Privy Council 'On the Relation of Phosphorus and its Manufactures to the Question of Public Health.'⁸

That the cause of the maxillary necrosis and exfoliation occurring among the artisans employed in making lucifer-matches is the fumes of the phosphorus need not be discussed; the question has been already settled; and the reader is referred to the writings of the authors above named, especially Von Bibra and Geist, for the consideration of this point. The only question on this head which deserved serious inquiry arose from the fact, that the phosphorus employed was often impure, and contained a notable quantity of arsenic; and this Martius and Dupasquier considered might be the essential cause of the malady; but this supposition was not found to hold good under more critical and extended examination.⁹ It is only when the cause

¹ *Guy's Hospital Reports*, 2nd series, vol. xii. p. 163. London, 1847. This case occurred in the hospital practice of the late Mr. Aston Key, who, as Dr. Wilks informs the author, was already aware, from his own observation, of the essential nature of the disease and its relation to its peculiar cause.

An admirable digest of this subject has been published, in the shape of a review of Von Bibra and Geist's work, in the *British and Foreign Medico-Chirurgical Review* for April 1848.

⁸ 'On the Manufactories in which Phosphorus is Produced or Employed,' in the *Fifth Report of the Medical Officer of the Privy Council*, p. 162. London, 1863. I may mention that my article on this subject in the first edition of this work was in type before the publication of Dr. Bristowe's Report, though from the delay in the issue of the fourth volume it did not appear till a year afterwards. But Dr. Bristowe was furnished with a copy of the article, from which indeed he makes quotations.

⁹ The actual agent in producing the phosphorus disease is doubtless oxidised phosphorus, probably in the form of phosphorus or phosphoric acid, dissolved in the saliva. The precise nature of the fumes is not exactly known; they consist principally of phosphorus acid (H_2PO_3), which by mixture with air becomes phosphoric acid (H_2PO_4), and probably minute quantities of phosphorus-vapour (P), phosphuretted hydrogen (H_2P), and hypophosphorous acid (H_2PO_2), are also present. Any vapour of phosphorus and hypophosphorous acid would be speedily converted by the air into phosphorous and phosphoric acids. Phosphuretted hydrogen would be more slowly oxidised into the same products. At any rate, nearly if not quite the whole of the fumes when inhaled by the workpeople would be in a state of some acid of phosphorus capable of being fixed and neutralised by an alkali. Such being the case, it is greatly to be regretted that efficient sanitary measures are not adopted to prevent the disease, which surely might be done. The recommendations of Geist and Roussel amount simply to cleanliness and ventilation, and are not sufficient. I would suggest, that in all lucifer-match manufactories there should be a periodic and rigid scrutiny of the mouths of all the workpeople employed. Those having faulty teeth should be excluded from the rooms (the dipping and drying rooms) where the obnoxious fumes are being developed. All carious teeth should be extracted or plugged. What is more important—a very simple and

has been long in operation, and under circumstances of great intensity, that the disease is developed; it is confined almost entirely to those who are employed in the process of *dipping* the matches into the fused and reeking phosphorus compound, and those who dry them in the same apartment. Moreover, a long exposure to the influence is necessary for the production of the disease. Lucifer manufactories had existed eleven years in Vienna, when in 1839 Lorinser observed the first case which attracted attention; and the shortest known period in which the malady has developed itself was in an instance which occurred in Paris, and is recorded by Gendrin, in which the patient had been employed in the occupation two years before the first symptoms appeared. Another circumstance of curious import, though not invalidating the generally-received doctrine of local poisoning, is, that the sufferer may have been removed from the baneful influence for a considerable period, and nevertheless be subsequently attacked by the disease.

Strohl gives an instance of a girl who had worked as a *dipper* at a lucifer-match manufactory for five years; she left that employment, and adopted a totally different and healthy occupation, when, after three months, she was, for the first time, attacked with unmistakable symptoms of the phosphorus disease, ending after fifteen months in exfoliation of portions of the superior maxilla.

It is very seldom that others than those employed in making lucifer-matches suffer from this malady; but that this may happen should not be lost sight of.

Pluskal¹ mentions an example of a little girl, seven years of age, who was in the constant habit of playing with matches, standing before a wall and discharging them in the dark for amusement, so that her face was bathed in their fumes; in time she was attacked with necrosis and exfoliation of small portions of the front of the lower jaw, with the ordinary attendant symptoms. Simon narrates a case in which the disease appears to have been brought on by a person chewing pieces of ginger, which he kept in his pocket with some lucifer-matches. And Sir J. Paget describes² a case in which the malady was induced by the manufacture of medicines in which phosphorus was employed.

The influence of the phosphorus fumes upon the jaw is undoubtedly local. Lorinser, who has the merit of discovering this disease, held a different opinion; but Roussel, Geist, and indeed subsequent writers generally, have adopted the opinion, which all the evidence upon this point seems clearly to establish.³ I have not space here to enter upon the argument of the question, I may, however, mention one telling fact; it is, the necessity of dental curies in the individual before the disease can be produced. It has never been known to occur, excepting where the sufferer has had carious teeth; and many persons have worked in the manufactories for a long series of years with perfect impunity, who, upon the supervention of dental caries, have been attacked with the malady. Dental caries, by opening the central chamber of

effectual respirator for the mouth might be worn by the employes; it would be unnecessary over the nostrils. It should be constructed on the ordinary plan of respirators, but its centre consisting of a porous diaphragm, such as sponge or some woven fabric, linen or cotton, which should be daily dipped in a solution of one of the fixed alkalis or their carbonates. This would arrest nearly, if not quite, all the acid fumes of the phosphorus. Or the respirator devised by Mr. Graham for persons exposed to carbonic acid vapour would probably be as efficacious. It consists of the mixture in equal bulk of fresh-slacked lime and sulphate of soda, through a cushion of which it is easy to breathe. The wearing of some such respirator should be compulsory with the dippers and dryers. Again, the acid vapour might be neutralised and rendered innocuous by keeping the atmosphere of the apartment ammoniuretted. I believe, if these precautions were adopted, the disease would seldom, if ever, manifest itself.

There is a curious modification of phosphorus, known as 'amorphous' phosphorus, which does not emit noxious fumes when heated sufficiently for its employment in match-making. This kind, however, is not mixed with chlorate of potass (which furnishes the oxygen) for tipping the matches, but is employed to coat the rubber on the surface of the box against which, by friction, the chlorate of potass match is ignited. These matches deserve universal adoption; for not only are they made without possible injury to the workpeople; but they are quite safe, being incapable of accidental ignition.

¹ *Oesterreichische medicinische Wochenschrift*, No. 30. Wien, 25 Juli, 1846.

² *Medical Times and Gazette*, vol. i. p. 41. 1862.

³ The arguments bearing upon this question, and the conclusive inference to which they lead, are stated with cogent force in an admirable clinical lecture on this subject by Mr. Simon, in the *Lancet* for 1850, p. 41.

the tooth and exposing the pulp, seems to offer a tolerably direct channel for the poison to be communicated to the subjacent periosteum, and this, no doubt, is why tooth-destruction is a necessary pre-existing condition. What the precise nature of the action of phosphorus-oxide thus absorbed may be upon the bone is a matter of speculation; but the particular nature of the poison, entering as it does so largely into the composition of the skeleton, is a suggestive circumstance: perhaps, if accumulated by the periosteum, it may generate on the bone's surface a condition of chemical *superphosphate*, inconsistent with osteal vitality.

The *symptoms* of phosphorus-necrosis do not differ essentially from other forms of necrosis in the same parts: they are, however, not unfrequently accompanied by bronchial and pulmonary irritation from inhalation of the fumes: this has been especially pointed out by Sédillot, Gendrin, and Dupasquier.¹ And one of the patients whom I have seen, affected with this malady, has detailed to me symptoms of *spasmodic asthma* which occasionally supervened when he was employed for many continuous hours 'dipping' while suffering from a common 'cold' in winter weather. Barring this occasional manifestation of pulmonary irritation, the general health of these workpeople is remarkably good.

The symptoms of the jaw disease usually commence with what is supposed to be toothache, the pain being at first pretty much localised to some one tooth that is carious, and which is probably the channel by which the poison is introduced. The advance of the disease is generally slow at first, and, as it were, undecided—indeed, indefinitely chronic; the pain is inconstant, and not early attended with more serious symptoms; presently, however, it becomes more severe and erratic, extending vaguely about the side of the head and down towards the shoulder, and with this severer pain swelling and extreme tenderness occur; the integument near the affected region becomes red, tense, and distended, while the teeth feel elongated and intensely painful when brought in contact with their fellows of the opposite jaw, and they become very loose. The gums are swollen and livid, and this condition extends to the mucous membrane of the cheek. All these symptoms increase till suppuration is established, and with them, more or less, symptomatic fever is developed in proportion to the severity and extent of the disease: the patient has rigors and pyrexia, and is often thoroughly ill. The point at which the pus finds its discharge varies a good deal: the soft parts first become very boggy, especially the gums, and matter often escapes early around the necks of the loose dead teeth: when pointing externally, its approach is accompanied by intense glistening erysipelas-like redness of the integument. The discharge of the pus is attended with great mitigation of the patient's suffering. The pus itself is often sanious at first, and very fetid, having the odour characteristic of the presence of necrosed bone. The orifice of discharge frequently leads to long burrowing sinuses, especially where the lower jaw is affected; and through these the dead bone may be detected by a probe. The swelling which attends the disease is often very great, particularly when the lower jaw is necrosed: it is diffuse and widespread, encasing the external and under surface of the bone in a prodigious, dense, plastic exudation. In very severe cases, previous to the discharge of pus, while the inflammatory symptoms are at their extreme height, the whole head, except the summit of the scalp, is involved—the eyes are closed; the nose, and even the forehead, swollen; the cheeks, lips, neck, and throat, are one continuous area of florid intumescence. It is a curious circumstance that in the lower jaw the necrosis is attended with a very large and complete development of ossifying callus, whereas none is formed when the upper jaw is effected. The large plastic exudation which surrounds the base of the lower jaw becomes converted into a mass of supplemental bone, supporting the sequestrum, which is, for the most part, naked and bare within and behind, and connecting sound portions of bone at its extremities when the whole of the maxillary arch is not involved. Geist assumes that the particular region occupied by the osteophytic incrustation about the lower jaw is the result of gravitation—an idea altogether too mechanical: it is rather to be looked upon as a physio-

¹ *Gaz. méd. de Paris*, 1840, No. 49.

logical manifestation, and one element in that marvellous exhibition of the *vis medicatrix nature* which this repair of the lower jaw displays: the supplemental bone thus placed forms the best support for the sequestrum, and the least interferes with the functions of the mouth; while the absence of an ossifying callus at the upper and inner region of the maxillary arch offers the readiest escape of the dead bone through the thin mucous membrane which there alone covers it, and this without damaging the integument of the face.

As the bone becomes laid bare by the ulceration of the soft parts, it is observed bathed in ichorous pus, ragged and irregular in its surface, and of a dirty blackish grey colour; this latter condition is said to be invariable, as though characteristic; but it is not so, for although very general, I have seen specimens white and clean, and with the compact external layer of bone intact.

To return to the symptoms of the disease. When the extent of necrosis is very great, the constitutional disturbance is correspondingly severe; and in the early stages of the malady the patient may have intense fever, with delirium and agonising local suffering, the more distressing from the region which the affection occupies—interfering with or altogether suspending the action of the mouth, and, by the secretion of foul and fetid pus, producing nausea, ructus, vomiting. The looseness and projection of the dead teeth is another source of annoyance and distress; as the sequestra containing them emerge from the surrounding parts, their elongation and angularity much irritate the gums and cheek in contact with them. In the severest cases, general sphacelus of the soft parts about the jaw, with œdema of the face and neck, may supervene, accompanied, or not, by erysipelas; and death may then close a scene of terrible suffering. In other instances with a fatal issue, life is drawn out through many months of tedious illness, varied by different degrees of local irritation; till at length the patient, with vital endurance inadequate to the requirements of the disease, sinks, tabid and exhausted, under continuous hectic, and not infrequently with tubercular complications.

But the pathological changes may be more terrible than those already mentioned.

Dr. Fbel describes a case which occurred in the practice of Dr. Hervieux at the Hospital *Necker*, in which the patient, a lucifer-match maker, first had necrosis of the lower jaw, then of the upper, afterwards of the palate bones and the orbits, and lastly of the os frontis. He died with brain symptoms. Pus was found between the dura mater and the brain.

When the malady progresses to a favourable issue, which it does in the majority of cases, the dead bone gradually loosens and becomes detached; and this is generally anticipated by the falling out of some of the necrosed teeth. In the upper jaw the sequestra are usually more broken up and smaller than in the lower, and they are shed easier, not being held in and detained by ossifying callus, which is always wanting in the upper jaw. In the lower jaw the sequestra are usually more extensive, often including large portions of the body of the bone, not infrequently the ascending rami, and sometimes the coronoid processes, and even the articular condyles. The shedding of these sequestra is often hindered by the large surrounding ossifying callus which always forms when the lower jaw is the subject of this disease.

I may here mention that some stress has been laid upon the circumstance that the lower jaw has been more frequently observed to be affected than the upper. The learned reviewer¹ of Geist and Von Bibra's work has given much detail bearing on this point; he enumerates twenty-five examples in which the lower jaw was affected, to twenty-one in which it was confined to the upper jaw. In five cases which I have seen, the lower jaw was diseased in four, and the upper in one; whereas four, which occurred in the practice of a surgical friend, were confined to the upper jaw. In seventeen instances of which I have obtained particulars or seen specimens, nine were connected with the superior, and eight with the inferior maxilla. Dr. Bristowe in his investigations met with evidence of thirty-nine cases in the lower jaw, twelve in the upper, and five in both.

The results of phosphorus-necrosis, in cases which get well, are very various.

¹ *British and Foreign Med.-Chir. Review*, before cited.

As regards general health, the patient usually recovers with an elastic convalescence after the dead bone has been removed; but the physical condition of his maxillary apparatus is often terribly mutilated. When the front part of the upper jaw is affected, it is an absolute and unrepaired loss, miserably disfiguring the patient, altering the physiognomy most painfully; when it affects more hidden parts of the jaw, the loss is not less complete, though less conspicuous.

If the affection is confined to the inferior maxilla, the removal of the sequestrum leaves a supplemental bony representative, which, for a time, more than makes up for the loss of the dead bone, and for a long subsequent period efficiently performs the office of edentulous mastication, and supplies the wants of personal comeliness.

In some instances the whole of the lower jaw has been lost, excepting the articular condyles; and these apparently connected with the new bone, have established the joint requirements of the supplemental jaw; but in other instances (cases in St. Bartholomew's Hospital, and those mentioned in Geist's later work¹) even the articular ends have been shed with the rest of the sequestrum: still there has been joint movement, doubtless from a ligamentous attachment of the new bone.

This repair of the lower jaw is, however, generally but temporary; for after a time—often a considerable time—the new bone diminishes, by absorption, to a mere narrow arch, and ultimately there is scarcely enough bone to keep out the lower lip, and the chin is utterly lost. I have had an opportunity of examining this state of parts after the lower jaw had been removed ten years. Dr. Bristowe, however, mentions two instances, one after six, and one after ten years, in which the supplementary bone remained large and well formed; but he describes another in which, after eight years, the new jaw was scarcely bigger than the hyoid bone. How far the loss by absorption of supplemental bone may be prevented by supplying it with a function, through the means of artificial teeth, is a question of theoretical interest and of practical importance.

The treatment of phosphorus-necrosis of the maxillæ divides itself into that which is common to all bone-necrosis, and that which specially applies to the particular local affection in question. Upon the latter head alone I would remark.

In the early stages of the disease, when as yet it is not established, but its super-vention feared, it would be of the last importance to remove the patient from the cause of the malady; pure air should be sought, abundant cleanliness, with urinary and alvine excretants, resorted to, and all suspicious teeth extracted. When, however, the local symptoms—extreme pain, swelling, and indurated infiltration of the soft parts—develop themselves, and the disease has already passed its promonitory stage, it will be advisable to have recourse to more active measures. Upon this point I cannot do better than quote Mr. Simon's remarks in his admirable clinical lecture, already referred to, and in the justice and propriety of which I entirely concur: 'So soon as the second or inflammatory stage of the disease has thoroughly set in, the bone seems in every case to be irrevocably doomed to necrosis; and I would therefore recommend you, in the event of your being called to a case at the transition period between the two stages, when hypertrophy is passing into inflammation, to adopt without hesitation the most active measures for the relief of the periosteum and bone. Leeches and general antiphlogistic treatment may do good; but the consideration of the pathology of this disease, together with the analogy of other periosteal affections, leads me to believe that the only real chance of doing good would lie in still more energetic measures; and I would recommend you in any such instance to make with your scalpel free vertical incisions through the gum wherever tenderness and swelling exist; extending your line of cut upwards in the upper jaw, or downwards in the lower, as far as the structure of the parts will allow, bringing your incisions as near together as circumstances may require, and in every point carrying them clearly down to the bone, so as to afford the utmost relief and relaxation to the overloaded and tense periosteum. I believe that this method of procedure would be the nearest approach to an effective one for checking the inflamma-

¹ *Die Regeneration des Unterkiefers nach totaler Necrose*, v. L. Geist, 1852.

tory stage of the disease before it has reached an intensity which must inevitably destroy the jaw.'

When the stage of threatening has past, the extent of the inflammatory mischief appears to assert itself at once—the whole of that portion of bone which is subsequently the sequestrum appears to be stricken from the first. Prevention is at an end, and palliation rather than cure is indicated as the surgeon's mission. When pus has formed, it should be early conducted to the surface, and by judicious interference external scars may often be prevented by means of well-directed punctures within the mouth. The whole of the teeth implanted in the dead bone become loose, and apparently elongated; their doom is already sealed, and they should be extracted without delay, as they cause much irritation to the tongue and cheeks.

When the discharge has established itself, and the fœtid pus is pouring from the sinuses that communicate with the dead bone, abundant rinsing of the mouth should be had recourse to, not only in the form of mere washes with water to remove the filthy secretions, but astringent and deodorising lotions, such as decoction of cinchona, and solution of alum, solution of chloride of lime, and, still better, solution of permanganate of potass. As has been pointed out by Mr. Simon, the unhappy patients are sometimes so disabled as to be incapable of gargling out their mouths, and then little pieces of sponge may be used by them to wipe away the stinking discharges.

As regards the sequestra little can be done. Sharp projecting pieces of bone may be cut off by nippers; but the bulk of the dead bone must take its own time to be shed—often a very long time. It is a period of miserable suffering to the patient, and terrible constitutional exhaustion; but it cannot be shortened or its results anticipated.

In March 1862 I saw in the London Hospital, under the care of Mr. Adams, a patient who had been suffering from the disease, affecting the entire inferior maxilla; it had been going on two years and a half; the latter four-fifths of the time with the lower jaw, except probably the articular ends, dead and lying in the mouth, bare and ghastly, bathed in ichorous pus within its huge supplemental successor.¹

The sequestra of the superior maxilla are apt to be more detached than those of the inferior—divisible and smaller, and they can be brought away piecemeal; moreover, as the upper jaw is an attached, and not, like the lower, a floating bone (with muscles ready to displace its parts when the integrity of its arch is broken), its dead portions can be removed without jeopardising the relations of the rest of the bone. Therefore a little and early surgical interference may be employed without injury, and parts brought away which, if belonging to the lower jaw, had better not be interfered with. In the lower jaw the disease is usually so much more comprehensive, and its resultant sequestrum is so solid, that patient watching and palliative treatment are all that can be adopted generally till the very close of the case. Earlier interference might disturb the relations of the supplemental bone (the *natural splint*) and the portions of jaw still living, and by allowing the strong antagonistic action of the muscles attached to the two halves of the latter to act separately, lead to the permanent displacement of the elements of the maxillary arch. The articular ends of the bone often—indeed, in the majority of cases, though not always—escape the necrosis, when the whole of the rest of the bone may be destroyed; and this circumstance suggests an element of treatment which may much shorten the patient's suffering. When the necrosis has evidently passed up to the neck of the condyles, the bone may be removed by sawing or nipping across the neck as high up as possible

¹ The necrosed jaw was afterwards removed. The operation and its sequence were both unusual. The patient was placed in a kneeling posture, with the chin on a table, and, the mouth being open, the symphysis of the jaw was split down by a chisel and mallet. The right half of the bone was then seized by large strong forceps, and wrenched from the mouth with great force. After a week the same course was adopted with the left half; but this required still greater traction. The entire bone was thus brought away, including the condyles. Ten days after the first operation the patient was seized with secondary hæmorrhage, profuse and arterial, on the *right* side from the wound, where the first portion of jaw was removed. This necessitated ligature of the right common carotid artery. The latter operation was performed by Mr. Maunder, and the patient recovered perfectly. See *Med. Times and Gazette*, July 5, 1862.

(on either side, if both sides are affected), and then dividing the bone of the jaw at its symphysis; the two halves of the bone may be withdrawn, one by one, without any external wound. Should the condyles be necrosed and follow, no harm will have been done by the previous operation, and the patient's suffering will have been much diminished and curtailed. The division of the bone may be accomplished by a Hey's saw, or some modification of it improvised to suit the particular position of the required line of section. Various curved bone-nippers may also be devised to accomplish the same objects. The extreme and firm closure of the mouth sometimes renders this operation very difficult.

I need not dwell upon the general treatment of these cases as far as they are in common with those of bone-necrosis generally. The particular region affected, however, involving and disabling, as it does, the masticatory function, entails some modifications. In the long tedium of their course every effort should be made to supply, by suitable food, the deficiencies which suspended mastication entails—mashed meat, eggs, cod-liver oil, and such sustainants, should be abundantly employed; and iron salts, in moderate proportion, should, if bearable by the patient, be almost a matter of daily diet rather than an occasional medicine.

There is one point which I would allude to—more a matter of pathological curiosity than having any other bearing; it is the enormous amount of pus which these patients daily swallow and (apparently) digest; it must be many ounces, and this without any obvious detriment to health; the patient's condition being no worse than may be accounted for by the force of the local symptoms.

Exanthematous jaw-necrosis.—I believe that the necrosis and exfoliation of the alveolar processes and portions of the jaws in children, consequent upon the eruptive fevers, is essentially the same as the maxillary necrosis in the victims of phosphorus fumes, and that it is the result of the local application of a specific poison to the vascular parts of teeth. There is this difference, however, that in the cases we are now considering the poison is generated within the individual, but with affinities for certain structures and tendencies to action upon certain organs which give its morbid consequences an equally local character. Whatever opinions may be entertained as to the homological relations of the several tissues of the teeth to those of the general integument, there can be no question as to their being members of the dermal system, and as such we should *a priori* expect that they would share the consequences which attend those particular diseases which spend their chief force on the skin. There is one circumstance, however, that modifies such an anticipation; it is the low state of vitality of the teeth, and the extremely slight nutritional changes which occur in them when once they are formed, and which must consequently remove them to a great extent from those transient though potent influences which would destroy or morbidly affect vascular or rapid-growing tissues. But such a qualification does not apply to the conditions of the teeth during their development. From the time of birth till the eighth or ninth year, the jaw-bones are the seat of intense developmental nutrition in the formation of the teeth, and are among the most vascular parts of the body; about the middle of the period named, five years of age, the maxillæ contain no less than forty-eight developed teeth and developing tooth-germs. It is about this time that the poison of the exanthematous fevers appears to exert its most deadly influence on the dental system.

The form of necrosis affecting the alveolar edges of the maxillæ, and accompanied by the shedding of the teeth, which we are now considering, was, I believe, first recognised by myself¹ as one of the sequelæ of the exanthemata, and dependent necessarily on their previous occurrence. Many isolated cases of the affection have been described, and our museums contain specimens of the sequestra; but the supposed relation of cause and effect had not, so far as I know, been expressed before.²

¹ 'On the Shedding of the Teeth, and Exfoliation of the Alveolar Processes, consequent upon the Eruptive Fevers,' by S. J. A. Salter, *Guy's Hospital Reports*, 3rd series, vol. iv. Several specimens of sequestra from these cases have been figured by the author in the *Transactions of the Pathological Society*, vol. xi. pp. 209-215.

² The earliest recorded cases are mentioned by Fox in his *History and Treatment of the*

This affection is by no means common, considering the almost universal occurrence of the eruptive fevers. The very large population tributary to Guy's Hospital has only furnished me with twenty-three or twenty-four cases during the last nine years; and I have reason to think that even in this I have been disproportionately favoured.

The cases are all singularly alike. A little child has just recovered from one of the eruptive fevers, most probably scarlatina; the case has been in no way unusual as to its severity or its course; within six weeks or two months of the passing off of the acute symptoms, tenderness of the mouth is complained of, and the mother notices fetor of the breath. Upon inspecting the mouth, the gum is seen to be peeling from the edge of the jaw around the neck or necks of some temporary tooth or teeth; pus is discharging, and more or less dead bone is exposed. The denudation of the bone progresses rather quickly in depth, but usually not after the first in lateral extent; the temporary teeth at the affected part become loose, and often fall out. There is no swelling; and no ossifying callus is formed in the region of the necrosed bone. In a few weeks from the first of these symptoms, the sequestrum itself becomes loose, and is easily removed, leaving a large gap, and a raw granulating surface, which rapidly heals. The necrosis almost always includes the bone which constitutes the loculi containing the developing permanent teeth, as well as the alveoli of the temporary; but it does not go further, and in the lower jaw the base of the bone is very rarely affected. I have never seen such an occurrence. The disease is frequently symmetrical: when attacking the bone about the temporary molars on one side of the jaw (its most common situation) it often manifests itself immediately after on the opposite side, and sometimes in the same regions of the other jaw. The same symmetry is observed in the front of the mouth.

As far as I am aware, this affection only occurs after the eruptive fevers,¹ and scarlatina is its most potent cause. In the instances which have been under my own care, two were after small pox, five or six after measles, and fifteen or sixteen after scarlet fever. There is, however, nothing in the condition of the mouth to indicate which has been the precursor. The age at which this affection occurs is usually about five years: from three to eight are the extreme limits I have known.

The issue of these cases is simply comprised in the loss of a certain amount of bone with the contained teeth, and the consequent disfigurement. As the permanent teeth are lost with the temporary, the disfigurement is very great when it affects the incisors; but when the temporary molars and their successors, the bicuspsids, suffer, the damage is comparatively slight. I have seen two examples of adults where this has happened in childhood, and the alteration of the face has been wonderfully little: the first molar approaches very close to the canine, and the second and third molars come well forward into the mouth, filling out the cheeks, and exhibiting no external evidence of what has occurred. In one solitary instance which I saw, in which the permanent tooth was not shed at the time when the bone and temporary tooth were lost, it was in effect equally destroyed, for the tooth was blighted—it did not grow after that time; no fung was formed, and when cut it remained a mere toothcrown, loosely attached to the surface of the gum.

The treatment of these cases involves little beyond patience and cleanliness. No operative interference is indicated, the extent of the necrosis asserts itself from the first, and cannot be curtailed. Soon the sequestrum becomes loose, and may then be

Diseases of the Teeth, p. 112. London, 1806. These cases, two in number, occurred after small-pox.

¹ I have heard of one doubtful case after continued fever (typhus or typhoid); but this would form no real exception to these cases or their pathological interpretation. The continued fevers have their specific cutaneous eruptions; and their damaging influence on the tegumentary system is sufficiently attested by the falling of the hair in convalescents from them. I would not, however, be supposed to deny that jaw-necrosis, associated or not with death and exfoliation of other bones, may occur in children as the result only of extreme cachexia or depressed vital nutrition. I merely wish to assert my belief that the particular form of alveolar necrosis above described is one of the *specific sequelæ* of the eruptive fevers, and is related to its cause in the manner indicated in the previous pages.

readily removed by dressing-forceps. I would suggest a weak solution of *perman-ganate of potash*, as a cleansing and deodorising mouth-wash. Any general symptoms of disturbed health should be met on ordinary principles. Where the suppuration is profuse, and the bone-necrosis extensive, stimulants and tonics may be required; and in the scarlet fever cases steel would be a useful adjunct; but I would observe, that in the cases I have seen, the children were, for convalescents, in remarkably good health, and had, almost without exception, escaped the other ill consequences of the eruptive fevers.

IX. *Hæmorrhage after extraction of teeth*.—Long-continued and obstinate bleeding after the extraction of teeth is an occasional and troublesome complication of this operation. It is not a common consequence: indeed it is very rare, considering the enormous numbers of the operations, and how seldom in proportion continued bleeding follows them. The troublesome hæmorrhage from the wound of an extracted tooth is of a peculiar character: it is not a rapid arterial discharge immediately following the vascular rupture which the tooth-extraction causes, but a continuous, abundant flow of blood welling up in the empty socket, and developing itself into a serious and sometimes alarming symptom, usually many hours after the operation. The profuse pouring-out of vivid arterial blood which sometimes follows the drawing of a tooth has no relation to the circumstance we are considering; that generally lasts but for a few minutes, and then ceases. The continued hæmorrhage is not the discharge of any considerable arterial trunk that may have been wounded, as has been supposed, but the passive bleeding, as it seems, of the entire disrupted surface, from an inability of the vessels to accomplish the curative closure of their broken ends. In the majority of the recorded cases there has been distinct evidence of the existence of the hæmorrhagic diathesis in the individual affected; and in not a few the patients have themselves been aware of the tendency, from having experienced similar consequences attendant on the previous extraction of other teeth. Indeed, some persons (I have some such patients of my own) refuse to have any more teeth removed, preferring rather to suffer any amount of toothache, on account of the alarming hæmorrhages which have followed the operations before.

In one case which came under my treatment, there was no history of a hæmorrhagic tendency: but the patient was a young lady, and the circumstance occurred just as menstruation was imminent. The bleeding was very considerable, and continued for two days, when under the influence of emmenagogues (hot hip-baths and aloetic purgatives), the catamenia appeared, and the hæmorrhage from the alveolus immediately ceased. In this case, doubtless, the bleeding was a vicarious manifestation of the periodic function. A very interesting example of this distressing consequence of tooth-drawing, showing its constitutional nature, was under my care some years since. A clergyman from one of the midland counties came to town to me on account of the hæmorrhage which had followed the extraction of a lower molar tooth three or four days before and was still continuing. He was reduced to a pitiable condition of exhaustion and bloodlessness. All the local means usually adopted had been tried, but without success: the bleeding, however, speedily ceased under the use of large and frequently-repeated doses of *tannin*. The history of this gentleman and his family is curious and instructive. As a boy, from the most trivial accidents, such as a cut finger, he sustained prolonged and almost irrepressible bleeding: during his whole life, the slightest blow or bruise would cause a large and very disproportioned ecchymosis; a few years before, he had sustained a week of hæmorrhage after the extraction of a tooth. This gentleman has three married sisters, all of whom suffer from terrible floodings at the birth of each child. He has a little boy, as liable to bleeding from a trivial wound as he was in his childhood.

It is of special importance to bear in mind the general and diathetic nature of alveolar hæmorrhage, in devising its proper treatment. Anything which would increase the wound, or add a fresh one (such as the cautery or the ligature of an arterial trunk), is contra-indicated.

A fatal example of alveolar hæmorrhage, in which both these means were adopted, is recorded in an early number of the 'Transactions of the Royal Medical and Chirurgical Society of London.' The previous history of this patient is singularly like that of the clergyman whose

¹ 'A Case of Fatal Hæmorrhage from Extraction of a Tooth,' by Richard Blagden, *Med.-Chir. Trans.* vol. viii. 1820.

case I have just mentioned, in the hæmorrhagic diathesis manifesting itself in childhood, and his having sustained a terrible loss of blood—the bleeding lasting for twenty-one days—when another tooth was extracted before. In the treatment of this fatal hæmorrhage, the actual cautery produced only a temporary arrest of bleeding; it was then determined to tie the carotid artery; the operation was performed by Sir B. Brodie, without any relief to the original symptoms; the wound in the neck only furnished another bleeding surface, and evidently hurried on the fatal catastrophe. In another recorded case where the cautery was used, the edge of the lip was accidentally burnt, and the surface thus cauterised soon commenced bleeding profusely, and continued to do so till the fatal termination of the case, which was hastened by it.

The *treatment* of this form of hæmorrhage divides itself into local and general; the local treatment consisting in the application of styptics, with continuous pressure upon the bleeding surface; the general treatment, in the rapid and abundant administration of internal astringents. The local plan of a plugging compress, recommended by Hunter, is that now universally adopted: 'In general it will be sufficient to stuff the socket with lint, or lint dipped in oil of turpentine, and to apply a compress of lint, or a piece of cork thicker than the bodies of the adjacent teeth, so that the teeth in the opposite jaw may keep up a pressure. It has been advised to stuff into the socket some soft wax, on a supposition that it would mould itself to the cavity, and so stop the bleeding: this, perhaps, may sometimes answer better than the other method, and therefore should be tried when that fails.'¹ The restoration of the extracted tooth to the socket has also been tried with success. For the purpose of forming a plug of lint, a strip should be cut of an elongated wedge-shape, and this should be introduced, the pointed end first; the extremity should be introduced into the bleeding socket, and driven well home to the bottom; the strip of lint should then be folded and re folded upon itself, so as to make the plug very solid and pressing on the entire superficies of the socket. When the compress of lint or cork has been applied, the mouth should be closed and the jaws kept permanently together, so as to exert considerable and persistent pressure by means of a broad bandage tied under the chin and over the head. Where the opposing teeth in the other jaw are wanting, it may be difficult to keep up the compress-pressure by the mere closure of an edentulous jaw upon the bleeding alveolus. Mr. Higginbottom of Nottingham was, I believe, the first to invent what he called an *alveolar tourniquet*.² It is an instrument consisting of two blades, or shafts, united at one end, and capable of approximation and compression by means of a screw, and free at the other extremities; these latter are armed with pads, one applying to the compress in the mouth, and the other to the exterior: where the bleeding is in the lower jaw, the blades are nearly equal, the exterior one simply passing under the base of the horizontal ramus: for the upper jaw the instrument is less applicable, and the outer blade requires a long curved sweep, so as to grasp the top of the head. Various local astringents have been recommended in conjunction with the lint-plug: matico has been highly spoken of: I have found an alcoholic saturated solution of tannin answer the purpose very well; but probably the old remedy, turpentine, has never really been superseded.

I am convinced, however, that it is a great mistake only to treat these cases topically: they are most obviously manifestations of constitutional vice, and require a corresponding general treatment. Astringents should be had recourse to at the earliest stage; they can do no harm, and may be suspended at any time, while in the majority of cases they will be most beneficial. These cases often extend over so long a period that constitutional treatment has abundant time to be brought into full operation. Tannin and turpentine have been the most successful of internal remedies in recorded cases; with the latter drug, steel might be advantageously combined, especially in the form of the muriate tincture. In the irritability of sanguineous exhaustion, opiates may become necessary in large doses.

¹ *A Practical Treatise on the Diseases of the Teeth*, by John Hunter, p. 92. London, 1778.

² 'On Arrest of Bleeding after Extraction of Teeth,' by J. Higginbottom, F.R.S., *Prov. Journ.*, vol. iv. 1842.

Other circumstances require attention : the patient should occupy a cool apartment, and local icy applications may be beneficial. Unless contra-indicated by faintness or excessive loss of blood, the upright posture is to be preferred : or if the patient goes to bed, he should be bolstered up in as elevated a position as possible, while the circulation in the lower extremities should be encouraged.

In women during the menstruating period of life, it should not be forgotten that the hæmorrhage may be associated with suppressed menstruation, and constitute a vicarious discharge ; and remedies should be adopted to meet this contingency.¹

X. *The application of obturators and false palates in cleft palate, &c.*—The title of this section is scarcely in keeping with the heading of my essay—‘Surgical Diseases connected with the Teeth,’ &c. The maladies which give rise to perforations and clefts of the palate are, practically speaking, very seldom dependent on diseases of the teeth ; but the particular region of their resultant defects, and the nature of the mechanical dentist’s art, as remedying those defects, bring this matter fairly within my province.

The two forms of cleft or perforate palate, congenital and induced, are very unequally suited to this particular plan of treatment ; a large number of the former may be radically cured by means of surgical operation, which is always preferable where practicable ; in the latter cases, the mechanical assistance of obturators is of more avail, and, in many instances, not only removes an existing defect for the time being, but is to a great extent curative.

In congenital cases, when *very* severe, this is the only method applicable for the treatment of the great physical defect, no operation being capable of bringing into apposition the separate masses on either side of the cleft, or of remedying the defect of soft parts, which consequently require to be supplied by new and foreign material.

When the cleft or perforation consists of an aperture in the hard palate only, as in most syphilitic and scrofulous cases, and some congenital, an arch of metal or other hard substance spanning over the orifice, and firmly applied to the contiguous palatal surface, is all that is required. When, however, it extends backwards and involves a destruction of the velum palati, and that to an amount which cannot be remedied by surgical operation, it becomes necessary to add to the metallic arch an elastic flap (such as vellum or india rubber), which will supply the mobile functions of the soft parts as they are when in a normal condition. The former apparatus may be styled *obturators*, the latter *false palates*. In not a few of these cases other portions of the upper jaw become implicated ; the alveolar processes may be necrosed, involving the loss of the contained teeth and sometimes considerable masses of bone. To replace these losses various combinations of obturators, false palates, and artificial teeth have to be constructed, and they may be made in every variety, the different parts being associated together to supply lost parts and to fit by close adjustment those that remain.

The materials of which obturators are made may vary ; carved ivory, vulcanite (indurated sulphuret of caoutchouc), or flattened metal—gold, platinum, dental alloy, or silver—are all employed. The first, however, is now generally discarded, from its perishable nature. Vulcanite has been extensively adopted, but its thickness, and fragile character when very thin, militate against it in many cases. I much prefer sheet metal, on account of its strength, thinness, and durability. Silver, platinum or dental alloy may be employed for hospital purposes ; but gold is far better, and I am in the habit of using it, except in hospital cases. It is an object to have the sheet of metal as thin as possible without weakening it ; and I employ the gold plate reduced to No. 6 of the gold-flatter’s gauge, being somewhat thinner than is usual for the frames on which artificial teeth are mounted. This degree of tenuity is quite compatible with entire firmness, and it receives better all the inequalities of the rugous palate : when a plate of this thickness is perfectly adapted to the palatal arch, it is scarcely appreciable to the wearer. As long as sound teeth remain in the

¹ On the Hæmorrhagic Diathesis, see vol. i. pp. 718 *et seq.*

upper jaw to which the plate may be attached, it should be supported by means of clasps or collars embracing them; when these are lost, the same object may be achieved by connecting the obturators by means of springs with a frame resting on the lower jaw. Under no circumstances whatever ought support to be obtained either by dilating sponge, or by hooks, or other processes passing into the nasal cavity—the effect of which is to increase the size of the orifice, or prevent its natural tendency to contract. The ¹ old and still very common method of treatment, consisting of a disc of metal with a piece of sponge attached to its upper surface passing into the nose, cannot be sufficiently reprehended; it is filthy in its nature, and most injurious to the unfortunate patient's future condition, as the pressure of the expanding sponge causes progressive absorption of the margin of the orifice to an unlimited extent. Any plug kept in position by tight-fitting acts in the same manner. There is a preparation in the Museum of St. Bartholomew's Hospital (ser. 1. no. 232) of the skull of a person who lost a portion of the palate, probably by syphilis, and who obtained temporary relief by stuffing the oro-nasal aperture with a large cork, gradually adding to the size of the plug to meet the requirements of the ever increasing orifice, till the whole of the hard palate had disappeared, the palatal processes of the ossa palati as well as those of the maxillæ being lost. The progressive absorption under this continually-advancing pressure had removed the vomer, the inferior turbinated bones, and the nasal wall of the maxillary sinuses. Such a specimen is an eloquent commentary on this reprehensible plan of treatment. I believe in no instance is it necessary to gain support by the passage of processes of any kind into the nasal cavity, either to wedge against the sides of the orifice, or to rest upon the nasal surface of the palato.

But an obturator passing over the perforation is not negative in its effect. An orifice which, allowed to remain open, may continue *in statu quo*, or contract in a degree scarcely appreciable, will often rapidly diminish in size when the passage of air and fluid between the oral and nasal cavities is prevented. This is not generally known or understood; but it is of great importance in treating these cases. The obturator should be applied as early as possible—as soon as the dead bone has come away, and while the wound is in a state of granulating activity. It is surprising how the granulations will stretch across the upper surface of the obturator, and close up the orifice; and, in more advanced and neglected cases, the same condition may be

¹ Among the earliest surgical writings we find notices of mechanical appliances to repair lesions of the palate. The still common obturator, consisting of a metal disc supported by a sponge passing through the perforation into the nose, was invented by Ambrose Paré, an eminent French surgeon (*Les Œuvres d'Ambroise Paré*; à Lyon, 1541). These and analogous apparatus on the same objectionable plan, were alone employed until Bourdet devised others on correct principles (*Recherches et Observations sur toutes les parties de l'Art du Dentiste*, par M. Bourdet; Paris, 1767). Bourdet employed thin sheet metal in the form of a vault wholly within the mouth, attached to the teeth at the sides, and free from any projection into the nose; and he was aware that when thus treated the orifice would contract and frequently close. M. Pierre Fauchard appears to have been the first person who combined artificial teeth with an obturator (*Le Chirurgien-Dentiste*; Paris, 1786). M. Touchard published an account of an apparatus not only to supply teeth and palate, but also a large mass of upper jaw which had exfoliated. This was effected with ivory (*Description d'un obturateur dentier présenté à la Société de Médecine de Paris*; Paris, 1814). M. Delabarre was the first person who succeeded in supplying a soft as well as a hard palate. He accomplished the former with sheet caoutchouc, as have nearly all his successors (*Traité de la partie mécanique de l'art du chirurgien-dentiste*, par C. F. Delabarre; Paris, 1820). But the greatest advance in the construction of false palates was made by Mr. Snell, whose apparatus was essentially the same as those employed in the present day (*Observations on the History, Use, and Construction of Obturators, or Artificial Palates*, by James Snell; London, 1824). The same principles have been carried out, with slight modifications, by Mr. Stearns (*Lancet*, vol. ii. 1845. pp. 7, 260, 284, 310); and by Mr. Sercombe ('Cleft Palate; its Surgical and Mechanical Treatment,' *Trans. Odont. Soc.* vol. i. London, 1858). Dr. Kingsley, of New York, has devised an ingenious arrangement which very firmly and effectually closes the cleft of the palate. It consists of a wedge-shaped plate of hard vulcanite with a soft velum, forced forward into the fissure, and resting by a ledge upon the nasal surface of the hard palate, thus reverting to the objectionable principle adopted previous to the time of Bourdet ('On the Treatment of Congenital Cleft Palate,' by Dr. N. W. Kingsley, in *Trans. Odont. Soc.* vol. v. p. 195; London, 1865).

imitated to some extent by frequently scarifying the edges of the perforation, always taking care immediately to restore and keep in place a well-fitting obturator. Why the removal of the ill effects of a perforate palate (passage of air and fluid from nose to mouth, and damaged voice), by means of mechanical appliance, should lessen or remove its cause, is not very apparent: it seems a curious transposition of events—an inverted sequence: perhaps the protection afforded by the plate to the granulating edge may to some extent account for it: it is, however, true, and very important practically.

Occasionally a portion of the floor of the antrum is lost by necrosis in cases of severe 'abscess' of that sinus, and its cavity becomes common with that of the mouth, by an aperture of variable size. This orifice should be immediately closed, or rather spanned over, by a plate (upon which substitutes for the lost teeth may, or may not, be fixed), and the result will be, in many instances, the development of a membranous growth supplying the lost bone, completely scarring over the wound, and forming a floor to the sinus. Mr. Coleman records an instance in which an orifice into the antrum, through loss of bone, scarred over and closed under the influence of the thermal cautery repeatedly applied.¹

The exact nature and arrangement of the artificial appliances we are considering will perhaps be best elucidated by illustrative cases.

The accompanying figure (fig. 117) represents the upper jaw of a girl who has recently lost a portion of the hard palate from the effects of inherited syphilis. This cause is, I believe, unusual. I have not seen or heard of another case in which

FIG. 117.

FIG. 118.

congenital syphilis has had such a result. The patient has suffered from characteristic keratitis, as well as from other symptoms of the disease. The loss of the bone was attended with all the customary conditions of suppuration and fetor, and after it came away a hole into the nose was left, as depicted in the woodcut. The patient's power of speech was seriously affected, and food and drink passed into the nose. A few days after the bone came away, I took a model of the mouth, and an obturator plate was made as represented in fig. 118. The girl being an hospital patient, the metal employed was 'dental alloy,' an alloy of silver and platinum, being less costly than gold. Support for the plate was obtained by collars passing between the bicusps and first molars and the bicusps and canines.

The application and fixing of the obturator *immediately* restored all the functions of the mouth: food was occluded from the nose, and articulation and enunciation were perfect.

This immediate restoration of the voice nearly always, I believe, occurs when accidental perforations of the palate are thus treated, and very soon, even where the soft palate is involved in a cleft and an artificial velum has to be supplied. But with congenital causes it is very different; and the patient has in them to commence a new oral education.

I saw this case again about three months after the introduction of the obturator:

¹ *Lancet*, Oct. 1, 1881, p. 613.

the hole had contracted to less than half its original size, and will probably close altogether.

The apparatus needed to supply the defects of cleft palate is more complicated, but is scarcely less satisfactory in its ultimate results. The accompanying figure (fig. 119) represents the upper jaw of a young gentleman, now about seventeen years of age. He was born with cleft palate and hare-lip. The latter was operated on in early infancy with success; and it was intended that the cleft in the palate should ultimately have been closed by surgical operation, but the patient refused to submit to the pain. The cleft is complete from before backward, passing to the left in the front of the month—an incisor being there wanting, as is frequently the case.

No difficulties were presented in adapting a hard and soft palate to occlude the cleft. A thin rigid gold plate was fitted to the hard palate, and support was obtained

FIG. 119.

FIG. 120.

by clasps between the bicusps and the teeth on either side, and to prevent the dropping of the hinder part, which is frequently troublesome, fine thin clasps extended round the back molars. The velum palati was replaced by thin soft vulcanised caoutchouc, which I always employ for this purpose. The accompanying illustrations (figs. 120, 121), showing the artificial palate as seen in face on the oral surface and in profile, render any lengthened description unnecessary. In adapting a soft palate it is necessary that the movable flap should be kept constantly in apposition with the pillars of the forces during their movements in deglutition, &c., and this is effected by means of an elastic spiral cord of gold wire, as seen in the profile illustration. This must be of the lightest possible character, as the power of the muscles to move the flap is very feeble. The same object is sometimes effected by doubling the thickness of the caoutchouc near the hard palate.

FIG. 121.

When a false soft palate is first introduced, it often produces tickling of the fauces and retching; and it answers well to employ a very small flap at first, and gradually increase its size till it amply replaces the deficient velum.

When the flap is made of soft caoutchouc it becomes sodden in time and loses its elasticity; but it is easily replaced, and an intelligent patient may do this for

himself. To obviate this objection, Mr. Parkinson,¹ who has had much experience in treating these cases, employs a thin flap of vulcanite; but this being stiff can hardly apply itself so closely to the pillars of the fauces; still, in effect, it is said to answer well.

In cases where large portions of jaw are lost from disease or accident, admirable restorations may be made, especially by means of vulcanite, and there is scarcely any part of the mechanist's art which tells with more effect on the patient's comfort. It is scarcely possible to put a limit to the variety and extent which these useful apparatus may reach.

S. JAMES A. SALTER.

DISEASES OF THE MOUTH, PHARYNX, AND ŒSOPHAGUS.

INFLAMMATION OF TONSIL. QUINSY. CYNANCHE TONSILLARIS.

THE most common morbid affections of the tonsils may be thus classed :—

- 1st. Acute inflammation and abscess.
- 2nd. Chronic inflammation and enlargement.
- 3rd. Ulceration and sloughing.

1. *Acute inflammation* of the tonsils is generally preceded or attended by a distinct rigor or chilliness, and general feverish disturbance. Accompanying or following such constitutional irritation will be found pain in the fauces, and tenderness of the upper part of the throat in every effort at deglutition. The pain at first is not acute, but rather as if the parts had been bruised, and is diffused over the back part of the mouth and the pharynx. As the case progresses, the local mischief becomes more evident. At first a mere blush, the redness of the part becomes more marked. With the altered colour of the mucous membrane, tumidity of the tonsil will be observed, and before long œdema of the surrounding soft structures. With the increase in the severity of these local changes, it usually becomes evident that the mischief is confined to one side. But the evils of inflammation of the tonsil are not restricted to these symptoms alone, nor do the sufferings usually stop short here. Pains in the jaws and headache; fever and loss of appetite; often severe suffering in the part affected; a loaded, creamy, and swollen tongue, with very foul breath; muffled articulation; great difficulty in swallowing, and fluids attempted to be swallowed escaping through the nostrils, great fear of strangulation; the patient frequently obliged to sit forward, or lie on one side, to allow the abundant saliva to drip into a basin, or drain away on a sponge—these are the conditions which mark the progress of the complaint, and comprise the chief characteristics of the attack. As the attack advances, the local examination of the mouth detects an increase of swelling, which usually runs forward in the substance of the soft palate, and on the side affected; in aggravated cases even implicating the tissues which cover the hard palate as far forwards as the incisor teeth. With the increase of swelling, a central softening spot will sooner or later be detected, either with the eye, or more frequently at a comparatively earlier period, by an examination with the finger.

Much difference will be found, in different cases, as to the period at which pus is formed in an attack of acute inflammation of the tonsil, i.e. as to the period when the abscess may be relieved by incision. In some instances from forty-eight to sixty hours will suffice to insure such a desirable condition. In other cases, many days will elapse before matter can be detected by the point of the finger, or upon the thrust of a scalpel. During all this time the patient passes his days and nights in misery; is not able to take any solid food, and but little fluid nourishment; obtains very little sleep, and that little of a disturbed character; has difficulty in respiration, caused by more or less œdema of the glosso-epiglottidean and aryteno-epiglottidean folds, and often greatly aggravated by fear, and a nervous horror of approaching suffocation. Inflammation in the acute form attacking the tonsil seldom terminates in resolution: as a general rule, it runs into abscess. This abscess will burst sooner or later if left to itself; and when burst, the urgency of the symptoms will at once commence to subside. But if the abscess can be opened by the surgeon a day or two previous to what would otherwise be the spontaneous period of perforation, by so much will the patient's suffering be alleviated.

The causes of this form of inflammation appear to be generally associated with some disordered state of health, which renders the tonsils and throat especially susceptible to the influence of cold; for to direct exposure to cold may usually be attributed the immediate cause of an attack. But it will often occur that the patient has suffered from some constitutional disturbance previous to the commencement of the sore throat. Not infrequently he is of a gouty habit. Rigors and flushes commonly herald the attack, before the gland itself becomes the seat of inflammation. Abscess, the result of simple inflammation of the tonsil, irrespective of those cases which are complicated with scarlet fever, is a rare affection in childhood. It is seldom met with before puberty. It is not a frequent attendant on old age. It appears to be a disorder of youth and middle life.

It rarely occurs that both tonsils are simultaneously affected. But sometimes, after one tonsil has been the seat of suppuration, the opposite one becomes inflamed and runs into abscess. This, however, is infrequent. We occasionally meet with individuals who are subject to recurring attacks of inflammation of the tonsils and quinsy. These attacks occur every one or two years, often at shorter intervals; and then after a period this tendency appears to entirely subside.

Such conditions indicate especially, and prominently mark, the importance of constitutional treatment rather than simple attention to the local evil. It has constantly been found most serviceable, directly a patient has anticipated the recurrence of such an attack, to administer a stimulating emetic. The action of vomiting not only relieves by emptying the stomach, but appears also to have some beneficial action locally. In fact, individuals subject to such attacks, and who have adopted such a course of treatment, have expressed themselves satisfied that suppurative mischief has been warded off by recourse to an emetic in the very earliest stage of a sore throat.

As the attack is usually of a very debilitating character, an emetic of mustard is preferable, on every account, to one of antimony or ipecacuanha. Fomentations to the throat externally, inhalations of the steam of hot water pretty constantly, and a free purgation after the action of the emetic, should be the chief points of treatment. We strongly condemn the abstraction of blood, either locally or generally, either by leeches or by any other means. Blisters appear equally unnecessary, and are objectionable on account of the irritation and annoyance they entail on the patient. Mustard poultices appear to afford much relief in many cases; their application is often grateful to the patient's feelings; and by repeated application they can be made to keep up sufficient counter-irritation, without the inconvenience of producing a sore. A blister occasionally leaves a very red, irritable, and painful raw surface on the neck, which, added to the exhaustion following an attack of quinsy, may be a source of considerable distress.

This disorder is one that calls much upon the strength and vital powers of the patient. During the greater part of the attack, food is taken but sparingly, and that in a fluid form. It therefore behoves us to husband the forces rather than diminish them by heroic treatment. As there is much difficulty in swallowing, the less a patient is pestered with physic the less uncomfortable will be his day. At night it may be desirable to procure sleep, if he be restless; and for such a purpose a few drops of morphia by hypodermic injection will in all probability suffice. But the use of opiates in such cases is better avoided.

So much is the patient reduced by such an attack, that when the pus is evacuated by puncture, or escapes by an ulcerated opening, it will generally be found that some days of nutritious feeding are requisite before he regains strength and the substance he carried previous to his illness.

Local treatment is more open to discussion. Some writers advocate the free application of solid nitrate of silver to the surface of the inflamed membrane; but it is somewhat doubtful if any benefit is secured by this method of treatment. It is certainly attended by one disadvantage; it produces a good deal of local discomfort, a most disagreeable taste for some time, and gives rise to much hawking and spitting, until the superficial sloughs occasioned by its application are removed.

from the inflamed membrane. We have not found that the application, under the acute conditions described, is followed by any satisfactory or beneficial results.

If the swelling of the tonsil be considerable, the surface very red, and the part very tender, and yet no very distinct indication of pus be present, it may appear sometimes advisable to make a deep puncture into the part to relieve congestion; or one or two incisions less deep. But as a rule, if the urgency of the symptoms be not great, it is far better to wait the formation of matter, rather than experimentally adopt an exploratory use of the scalpel. Every sensible practitioner studies the feelings of his patient; every good surgeon avoids the uncertain or unnecessary use of the knife. Incisions, if made, often occasion much suffering, are especially dreaded by some who have previously submitted to such treatment, and seldom appear to hasten the escape of matter. When, however, pus is detected or suspected, the part should be at once punctured.

There are some few precautions requisite, when any pointed or cutting instrument is used to open an abscess at the back or side of the mouth. The knife itself need only have, from its extremity, a cutting surface of about half an inch. Whatever knife be employed, it is best to protect the blade so as to cover its cutting edge up to this extent, by wrapping round it, from the handle towards the point, a piece of rag or plaster. A sharp-pointed straight bistoury is of all knives the most convenient for the surgeon's purpose.

In passing the instrument, when protected as described, into, or on withdrawing it from the mouth, the risk of wounding the lips or tongue is necessarily lessened—we may say is avoided, for no such accident should occur in proper hands. On puncturing the tonsil or abscess, an important precaution must be observed. The point of the knife must be kept towards the median line, especially after its point is buried in the soft tissues, and out of sight; on no account is the direction of the wound or thrust of the knife to be outwards. By due attention to this simple caution, all risk of wounding the larger vessels lying on the outer side of the neck is avoided.

The patient's head should be fixed, either against the back of a chair, or by the hands of a third person. A sudden movement while the knife is passing into the tonsil might lead to grave mischief, as the instrument might accidentally and unavoidably be thrust in a wrong direction.

The mouth is occasionally opened with some difficulty; and the tongue may be so much implicated in the inflammation that the patient cannot, by his own efforts, sufficiently aid the surgeon to obtain a good view of the swollen tonsil. Under such circumstances, a broad spatula gently applied to the surface of the tongue will expose the part sufficiently to permit the abscess to be punctured in a satisfactory manner.¹

As soon as the abscess has been punctured, the pus generally flows freely on the withdrawal of the knife; sometimes so abundantly and so suddenly that it runs into the gullet; and from this circumstance, or from the fact that it is often very fetid, it greatly nauseates the patient, sometimes to vomiting. Shortly after the escape of the pus, the patient usually becomes comfortable, expresses himself wonderfully relieved, and soon desires to partake of food. Convalescence is generally rapid and satisfactory.

As we have already said, occasionally, but rarely, the opposite tonsil becomes inflamed and suppurates. Under such circumstances an early tonic and stimulating course of treatment may be requisite; and the medical attendant must look for his

¹ A practical hint in passing may here be thrown out, on the best method of examining the throat generally. With many patients it is often a matter of some difficulty to gain a sight of the fauces. The tongue is pushed upwards directly the mouth is opened; and when the spatula is applied with the intention of pushing down the tongue, the patient immediately appears to resist its application with a steady and firm effort. *If, however, the spatula is, without the slightest weight, laid on the tongue, it gradually contracts and is drawn backwards, allowing a perfect view of the fauces.* No force or pressure is requisite on the part of the surgeon to effect this; the weight alone of the spatula appears sufficient to insure the object desired. This experiment has been constantly illustrated, on patients suffering from throat-affections, to our pupils.

guide to those symptoms which would indicate constitutional deterioration and physical exhaustion, to be met by generous diet and wine or other stimulants.

In the treatment of all cases of abscess of tonsil, there must be a certain amount of anxiety : but the anxiety as to the symptoms which precede the formation of the abscess is as nothing compared to that we may have to encounter when unfavourable symptoms are set up *after* the evacuation of the pus. In an unhealthy constitution ulceration may supervene upon the incision, and be followed by sloughing sore throat ; or œdema of the surrounding soft tissues may arise, and travelling downwards around the larynx, pharynx, and œsophagus, terminate the patient's life in a few days. But fortunately these are the rarer evils following upon the evacuation of pus, the result of simple acute inflammation of a tonsil, or true quinsy ; the usual history of which complaint is, that directly the abscess has burst or is opened, convalescence is speedy and perfect.

The sore throat of childhood is rarely acute inflammation of the tonsil ending in abscess. It is usually the symptom or accompaniment of scarlet fever, or partakes of that more frightful and fatal character known as 'putrid' or 'sloughing sore throat,' of which we shall hereafter speak. The latter is usually accompanied by enlargement of some of the glands of the throat or parotid. In quinsy the throat-glands are seldom affected, and if affected, not to any extent.

Several of the symptoms referred to above, as indicative of the formation of pus in an inflamed tonsil, are present to some extent under conditions which are apt to be mistaken for quinsy.

A decayed or broken tooth will often set up a considerable degree of alveolar inflammation, and be followed by abscess of gum or corresponding maxillary region. This condition occasions much difficulty in opening the mouth ; the breath is fetid ; the tongue becomes very foul and loaded ; there is great difficulty in deglutition, and pain of face on the side affected. But generally one marked difference exists between the symptoms of quinsy and an abscess originating in alveolar inflammation ; when a tooth or a stump is the cause of the mischief, there is always more or less swelling of the *face*, and tenderness and swelling, especially over the *maxilla* affected. In quinsy, if there be external swelling present, it is not over the face or cheek ; it is confined to the submaxillary region, and the neighbourhood of the parotid.

In all cases of inflammation, either within or external to the mouth or throat, the medical attendant should look with suspicious care to the condition of the mouth. There are few circumstances in practice more apt to be overlooked than the evils which arise from the irritation of decayed teeth.

2. *Chronic inflammation*, terminating in enlargement of the tonsil and thickening of its mucous surface, is a very common condition, more especially to be observed in children, and in young persons of both sexes under the ages from twenty to thirty. The tendency to this form of diseased action and enlargement is mostly observed in individuals of a strumous or lymphatic habit. The enlargement frequently commences as early as the second year of life, and has been observed to occur more especially in children who have been weaned when very young, or brought up by hand-feeding. Less frequently it does not show itself until towards the period of approaching puberty. It has a tendency to affect females in a greater proportion than males, though it is by no means an infrequent complaint in the latter sex.

The commencement of chronic enlargement of the tonsils appears to be unattended by any marked symptoms, local or general. Rarely is attention drawn to the condition of the part until either the thickness of articulation, loud snoring in sleep, or deafness, excites the mother's curiosity, or gives rise to anxiety, when an examination of the throat is instituted. Pain is never a symptom attendant on these swellings. The only local symptoms are those which necessarily arise from the mechanical encroachment of the tonsils, in the median line, betwixt the external oral and nasal apertures, and the internal apertures of the breath- and food-passages. The intensity of these symptoms will depend on the size of the masses on either side of the fauces.

The causes which produce this chronic enlargement of the tonsils are not satis-

factorily established. A careful inquiry into the history of a large number of cases has failed to detect any one specific reason to account for this diseased action. It does not appear to depend on cold, or insufficient nourishment, nor on want of cleanliness; for it will be met with in the children of the upper, as often as in those of the lower classes, and as often in those who are well provided and tenderly cared for, as in those who are the children 'of sorrow and acquainted with grief.'

This diseased action does, however, appear to affect in a larger proportion those children who have been brought up by hand or early weaned, than those who have been supplied for a sufficient time with the mother's breast-milk. The enlargement of the tonsils will also frequently commence on the convalescence from severe attacks of the various eruptive or other forms of fever. Most frequently, however, their growth is grafted on a strumous diathesis.

The forms under which enlarged tonsils occur deserve some attention. One of the most frequent appears to be a uniform globular projection on either side, to a greater or less extent. In this condition the swelling may cease to grow, and remain stationary for years, without inconvenience or injurious consequences. Or the glands may slowly and steadily increase in size, until their surfaces touch below in the median space and above either side of the uvula. In other instances, the tonsils appear to enlarge towards the soft palate, and often upwards past its free border, as well as downwards so low that the lower end is hid from view by the base of the tongue, and is only with care detected when the latter is well depressed: or the tonsil on one side only may be seen to project, a perfectly round mass, which is attached to the fauces by a thin pedicle of mucous membrane: occasionally an outgrowth may be seen, a pendulous tumour hanging from the natural position of the tonsil.

The surface of an enlarged tonsil is generally somewhat uneven, often very much pitted; the mucous membrane thick and velvety, and seldom without an increased vascularity. In many instances all these conditions may be observed in an aggravated degree. Often, superficially ulcerated spots are seen dotting the surface of the swelling: or, what is more common, small points of thick sticky sebaceous secretion will be observed, adhering to the mucous surface.

The fauces, especially when the enlargement of the tonsils is considerable, may often be seen covered with a viscid yellowish semi-purulent secretion; this clings to the posterior surface of the glands, or lines the walls of the upper portion of the pharynx.

When the enlarged gland projects to any extent above the soft palate, some degree of deafness is occasionally complained of. This concomitant symptom may depend rather upon the thickened condition of the mucous membrane, which, extending from the tonsils, run up to, and even encroach within, the Eustachian tube, rather than upon any actual pressure of the gland on the orifice of the tube.

Enlarged tonsils appear to be the result, not the cause, of constitutional derangement, provided they do not become large, or occupy much of the isthmus of the fauces. But if they increase in size, and thus lessen the passage from the mouth to the pharynx, many unpleasant effects may be detected. The voice is generally somewhat unnatural and muffled, and the pronunciation thick. So that enlarged tonsils appear to be a perfect impediment to the production of fine sweet notes in song, or clear sonorous tones in speech. The breath is often offensive; partly rendered so by the decomposing sebaceous secretion sticking in the orifices of the glands, partly by the thick semi-purulent mucus which clings to the fauces.

The enlarged glands are constantly liable to attacks of ulceration, and sometimes to acute inflammation attended by fever. If large in children, they produce more general effects on the system than in adults. They now interfere with perfect and free respiration. At night the child snores loudly: often awakes in his sleep, and as often in a state of alarm. In some instances the natural and requisite amount of rest is so interfered with that the child's health suffers. There is also frequently some little inconvenience in swallowing, and care is observed to be taken by the child that only small quantities of food be swallowed at a time.

If a section of a portion of an enlarged tonsil be examined carefully, it will be found, to the touch, firm in consistence, and somewhat elastic when pressed. The face of the cut surface will present several small uneven and irregular depressions, from which may be picked, every here and there, or squeezed out, small collections of sebaceous matter. The structure of the enlarged mass consists of condensed areolar tissue, which often runs like bands between and around the depressions above alluded to. The naturally soft structure of the gland is so condensed and firm, that it assumes the character of fibrous tissue intersecting the substance of the growth in every direction.

The accumulation of epithelial secretion within the ducts of the glands, occasioned by the obstruction of their orifices, is the explanation of the formation of the cavities seen on a section of the gland; for, as the secretion increases, and cannot escape through the obstructed orifices of the ducts, it collects in the latter, dilates them, and sets up chronic inflammation of the structure of the gland itself, which terminates in its permanent enlargement.¹ This secretion will frequently be observed to escape from the surface of the enlarged tonsil when it is firmly pressed between the blades of the vulsellum prior to removal.

The treatment of enlarged tonsils may be summed up in a few lines. Unless the voice be affected to such an extent that it becomes desirable to lessen or remove them; unless the disturbance to the sleep of the child be manifestly interfering with health; unless the breath be rendered fetid or offensive by the secretion from the ducts; or unless some other cogent reason render it desirable to interfere with the mass—it is better to leave the tonsil in its slightly enlarged condition, without the application of any local or constitutional measures. If a child so affected be delicate, and the tonsils appear increasing, we prefer constitutional to all local treatment short of that of removal. In the early stages of enlarging tonsils, if detected, it would be best to administer tonics as a rule, as they certainly act beneficially as regards the health; and by so doing, as far as experience allows us to hazard an opinion, arrest the progress of the growth. At any rate, under a tonic treatment such enlargements frequently remain stationary. Steel-wine, muriated tincture of iron, citrate of iron, syrup of iodide of iron, and cod-liver oil, each according to the constitutional peculiarity, may be prescribed with safety, and taken with evident benefit for many weeks or months. We need hardly caution the reader on the importance of attention to diet; and with very weakly children, sea-bathing is of the utmost advantage.

Local applications are frequently recommended, and too constantly adopted. Nitrate of silver rubbed over the surface, or points of nitrate of silver run into the substance of the gland; sometimes nitric acid carefully applied to portions of it; stimulating gargles; and a variety of troublesome and useless applications, have had their advocates for the arrest or removal of these masses.² An examination of a portion of a gland removed by excision will show such structural changes, such a fibrous thickening of the finer areolar tissue, that it appears a useless waste of time and material to attempt to procure absorption of such dense tissues. Nothing short of an actual slough can do good, if caustic be used; no stimulating application can offer much hope of acting on such a structure; it is therefore best not to waste time or inflict pain by having recourse to such useless local measures. If constitutional treatment does not arrest, and local treatment be requisite, removal by guillotine or knife of a portion of the gland is the speediest, and, in our opinion, the only efficient remedy. The surgeon can remove all that is necessary in a few seconds; and the patient will be entirely rid of the consequences within a week after.

When the glands are so large that some portion must be removed, to relieve the symptoms of discomfort or distress from which the patient suffers, the operation is

¹ Kölliker has given a minute account of the pathological conditions of the tonsil, and the abnormal secretion of the gland under such changes; but as any transcript of his investigations would not add to the practical importance of this subject, we beg to refer those interested in the question to the original (*Manual of Human Histology*, vol. ii. p. 30, Sydenham Society).

² The use of nitrate of silver persevered with, in a case known to the author, produced considerable permanent discoloration of the skin.

simple enough in adults, but may be somewhat troublesome when necessary in a young child. Under the latter circumstances it will be found advantageous to place the patient sufficiently under the influence of an anæsthetic to enable the operator to introduce the guillotine. The removal of the necessary portion of the gland is then easily effected.

In the adult there is no difficulty in the operation, and the guillotine may be used without the aid of an anæsthetic. If both tonsils be enlarged, and this is usually the case, there is no objection to a portion of each being removed on the same day. With children it is preferable to do so, as the fear of an operation is much greater when a child has had any experience of a previous one. But in an adult it may be left to the discretion or wishes of the patient, whether the operation be completed at once or at a subsequent period. If the tonsils are very large, it is always advisable to take away a considerable portion of each. But it is by no means requisite to remove the whole of the projecting mass. If half of the mass be removed, and the cells thus laid well open, what with their becoming emptied, the relief occasioned by the incision through parts chronically inflamed, and the subsequent contraction of the cut surface by cicatrisation, the portion that is left shrinks and sinks into the side of the fauces, to give no further trouble to the patient.

After the removal of the mass, the patient generally suffers but little; or rather as one affected with slight sore throat. The precaution to be given is, to use soft food, and to avoid exposure to cold for a few days, when the cut surface will be about healed. Hæmorrhage rarely follows to any troublesome extent on this operation; but it may, and sometimes does occur. The surgeon, always anxious to avoid such a contingency, should take the precaution not to draw too much of the gland through the aperture of the guillotine. This may be regulated by so adjusting the fork of the instrument that it shall not project very much from the aperture when the cutter or knife is thrust home. Not more than half of the mass need be removed, and even as much as this only when the tumour is of considerable size. Such a portion will always be found sufficient for the ultimate relief of the patient, and the removal of all the previous disagreeable symptoms. In the practice of the author, such a proceeding has never been followed by troublesome hæmorrhage. Should hæmorrhage occur, iced water as a drink, or the mouth kept open for a time, may control it; or digital pressure may be requisite.

In children, hæmorrhage may be suspected only after it has continued some time, from the cheeks becoming pallid, and the little patient showing signs of faintness. If, on examination, any distinct vessel is seen to bleed, a ligature can be applied with a little care; or recourse must be had to pressure, if the bleeding is from the general surface. Occasionally the enlargement of the tonsil assumes a pendulous form, so that the greater portion of the mass hangs down behind and below the roots of the tongue. In such cases it will be found easier to remove the growth by seizing it with a vulsellum, and cutting off as much as requisite with a blunt-pointed straight bistoury.

We need only refer to the proposal to remove enlarged tonsils by the application of ligatures, to condemn the plan of treatment as tedious, painful, and productive of much offensive discharge until the slough separates.

3. *Tonsillitis maligna*.—Ulceration of an acute form attacking the tonsils, and rapidly running into sloughing of the fauces, is a very grave—often a most intractable—affection; and as rapid as it is unmanageable.

Sore throat is the first symptom complained of, and with it the patient probably expresses himself as feeling ill. Rigors, followed by feverish disturbance, will generally supervene. The tonsils will soon be observed to be of a dusky red colour, and swollen; and the surrounding soft tissues and uvula are already œdematous. There will generally be much pain, and some difficulty in deglutition. Patchy shreds of grey or yellowish membrane appear embedded in the surface of the tonsils. These, after a time, spread, unite, and become deeper, until a considerable portion, if not the whole, of the soft palate may become implicated in the spreading mischief. The discharge which accompanies this form of slough escapes freely from the nose; for, as

the havoc spreads, the passage of even fluids to the throat is rendered difficult, and is often entirely intercepted by the cedematous state of the cellular tissue around the root of the tongue—so that liquids taken by the mouth are rejected through the nostrils. The character of the discharge is usually most offensive and intolerable.

If the patient survives, large sloughs separate from the parts attacked, and a considerable granulating surface may soon be observed, marking the havoc of the disease which has passed. In this havoc the whole of the uvula, and a considerable portion of the soft palate, have been seen to disappear, the patient's health being subsequently perfectly restored; though there remain for life the permanent defect, the alteration of the voice, and the inability to articulate distinctly—the results of the local injury to the soft palate.

In the greater portion of severe cases of malignant sore throat, the probability is that they are specific, or only a type of the severer forms of scarlet fever. But still the surgeon's experience may be sometimes advantageously referred to in some of the stages of such cases; and for this reason we have taken a brief notice of them.

As in sloughing of other tissues, so in that of the throat, under all circumstances a stimulating and tonic treatment must be pursued; wine must be freely given. The internal use of opium, carefully administered, is generally attended by most satisfactory results. It first seems to do good by modifying pain, and this enables the patient to swallow more readily and easily than he would do without it, and consequently he is able to partake more freely of nutritious food. But, as in ulceration and sloughing of other parts, so in this class of cases, it certainly seems to influence the morbid action of the parts, and to help in arresting the process of destruction. With children it is best administered as laudanum; its effects must of course be carefully watched, and its use withheld as soon as any drowsiness manifests itself. The muriated tincture of iron is also a most useful medicine in such cases, and may be ordered with benefit in full doses; diluted with syrup it has the advantage of being small in bulk and not unpleasant in taste, a desideratum of no small importance when a child is the patient.

The local treatment in these cases is a matter of much importance. The author has found most benefit from sulphurous acid applied in the form of a warm spray every hour or oftener for a minute or two at a time, while the patient is awake; and persevered with until the sloughs separate, and healthy granulation is established. The spray is easily and readily used, it is most cleanly, not at all disagreeable, if not too strong a solution, but rather comforting to the patient, and is notably the most efficient disinfectant applicable under such circumstances.

The fœtor in all such cases is generally very marked and distressing. The room should be kept thoroughly ventilated, and a liberal supply of a solution of chloride of lime or soda placed in different parts of it. The occasional use of the sulphurous acid spray carried about the room will also help materially to improve the state of the chamber.

A superficial and less severe form of ulceration of the tonsils is a very common occurrence. 'Ulcerated sore throat' is a term so familiar, and a condition so well understood among the more industrious and often over-worked students of our hospitals and dissecting-rooms, that it requires but little description here. Pain and some difficulty in swallowing; a creamy tongue; soft, weak pulse; pallid face; loss of appetite, and often loss of sleep; much languor and pains in the limbs; tonsils congested, and somewhat swollen; small, irritable, superficial, and scattered ulcers on the fauces and tonsils; urine often loaded with phosphates: such are the chief symptoms found to accompany one of these attacks.

The treatment is well understood. Change of air; a stimulating gargle; a slight aperient if requisite (mercurials, however, to be generally avoided); the internal administration of bark and ammonia, and a nutritious fluid diet, with a few glasses of wine daily, may be said to sum up all that is necessary. Convalescence is generally satisfactory under such treatment. A mouth wash of the permanganate of potash is also most agreeable in such cases; or as a gargle, it rapidly renders inodorous offensive discharges. It may with safety be used largely as a gargle or wash in all throat affections.

'Relaxed uvula' is by no means an uncommon complaint. The term does not quite describe the actual state of the parts in their altered conditions; for the uvula may be thickened and not increased in length. Under such circumstances it occasions but little annoyance, and seldom requires attention. Or it may be lengthened without being thickened, and this is the most common evil; and then surgical interference is necessary.

The increase of size, or the elongation, appear to be as independent of the condition spoken of under the name of enlarged tonsil, as the two conditions are of each other.

The increase of size is usually accompanied by a thickened state of the mucous membrane, and often a slight tenderness of the part. Though the thickening may remain, the tenderness after a time will subside; and then the part is left in a permanently enlarged, though not in a persistently enlarging, condition. It seldom increases to an inconvenient size.

Should the symptoms which attend the first increase of size be troublesome, the simplest local remedy is to smear the surface once or twice with solid nitrate of silver; and constitutionally use such measures as the general condition of the patient will indicate to the observant practitioner. Usually the condition is one which is benefited by tonics. Elongation of the uvula appears to be generally dependent on an excess of mucous membrane; for the azygos uvular muscle does not often form any part of the increased growth. The mucous membrane may extend an inch beyond the extremity of the muscle, and hang down like a thin narrow slip of tissue, ending often in a point. When of this length, it extends behind the root of the tongue lower than it should do, and the point rests over or even enters the aperture of the larynx. This contact with the larynx is a constant source of irritation, and occasions a troublesome cough. Frequently the tickling of the fauces and pharynx produces nausea and a tendency to vomit. Patients sometimes, after food, on coughing, reject a portion of the meal taken. These symptoms are often attributed to other causes until the throat is examined and the condition of the part detected.

This elongation of the uvula is not often seen in children, but most frequently in the period of middle life. It is seldom observed in old age.

The remedy is as simple as the relief is certain. Removal by knife or scissors is the only treatment to be entertained for a moment. The point of the uvula is to be seized with a long pair of forceps, and cut off so near to the base as to leave the part of its natural length.

The patient may feel the throat a little sore for a day or two, but no treatment beyond ordinary care will be requisite. The uvula is very apt to be implicated in inflammation about its neighbourhood; and constantly, under such circumstances, becomes oedematous. This condition, however, is seldom confined to the uvula alone, but implicates usually the soft palate and adjacent tissues. It depends on erysipelatous or diffuse inflammation of the cellular tissue—a dangerous and often fatal affection, which will be found treated of in the essay on DISEASES OF THE LARYNX.

Cancerous ulceration of the soft palate or tonsils is not frequently a primary affection. Generally it is continuous with disease originating about the back part of the gums, cheeks, or tongue, and in either case offers no hope of benefit from treatment. The sufferer usually fails rapidly in health, emaciates, and dies early after ulceration is detected. Often death is fortunately accelerated by sudden and profuse hæmorrhage, the result of perforation of some artery implicated by the ulceration. Sometimes such hæmorrhage may be fatal though the disease be not at all extensive, as occurred in the case of a distinguished member of our profession.

Tumours of the soft palate and fauces are sometimes met with of a non-malignant character, and independent of inflammation. These usually consist of, 1. Fibro-cellular tissue; 2. Cysts; 3. Warty growths and other growths of a non-malignant character, occasionally met with attached to the soft palate, and growing apparently from the mucous membrane.

It has occurred to the author to have to remove such growths in two instances in young women; in both the growths commenced without being noticed, and were accidentally discovered; they were readily removed, and were found to consist of simple epithelial structure.

1. The small fibro-cellular tumours usually assume a pendulous character. They are painless; usually attached to the free border or upper surface of the soft palate; and are generally only detected when they become locally inconvenient by dropping down below and behind the root of the tongue. They are usually somewhat slow in their growth, and as they increase in size become more pendulous, often supported by quite a thin pedicle. They can be readily removed with scissors and forceps.

2. *Cysts* of these parts commonly contain thin glairy fluid, generally the result of obstructed muciparous ducts. They are readily treated by a simple free incision and a subsequent application of solid nitrate of silver, or a drop or two of nitric acid applied on a probe to the interior of the cyst.

Sebaceous cysts are occasionally found in the substance of the soft palate. They may be recognised by their yellowish white colour showing through the mucous membrane. They only require to be laid open, and the interior of the cyst touched for a day or two with a probe nipped in nitric acid.

The author was consulted some few years ago by a gentleman who had a tumour occupying the right side of the fauces; it had so much increased in size since its commencement that the uvula was pushed some way towards the left tonsil. The growth was about the size of a small orange, was lying immediately beneath the mucous membrane, and appeared to have sprung from the wall of the upper portion of the pharynx. It occupied the position of the right tonsil, and quite filled up the opening of the fauces on the right of the uvula, while in front it pushed forward the soft palate on that side. It had been growing some four years, as far as the patient could judge, and was beginning to give trouble in deglutition. It was somewhat elastic to the touch, and the mucous membrane was freely movable over it. It also appeared fairly movable at its base. It had been pronounced by some to be a cyst, but the introduction of a trochar proved its solid nature. The patient consented to its removal, which was effected without much difficulty. A free incision was made through the mucous covering, which was readily separated from the tumour by passing the finger around it. And thus the mass was isolated from its surrounding attachments with the exception of one small part at its upper and outer surface, where it appeared more firmly attached to the corresponding wall of the pharynx. This was, however, easily cut through and the mass removed. It turned out to be an enchondromatous tumour, easily breaking up into pieces. As to its origin, it occurred to the author that possibly it might have originated in a growth from the inner surface of the parotid gland which had made its way through some of the muscular fibres of the upper constrictor of the pharynx, and then gradually increased till it attained the size when removed. There was no recurrence of the growth when the patient was seen three years after the operation.

Abscess of the soft palate is rare, but it should be opened as soon as detected. It generally gives no subsequent trouble.

‘CONGENITAL FISSURE’; ‘CLEFT PALATE’; AND DEFECTS OF THE PALATE FROM DISEASE OR ACCIDENT.

The occurrence of congenital fissure of the palate is so frequent; the evils which result from it are so marked; and the life of an infant is so often endangered and not unfrequently cut short when the fissure is extensive, that a consideration of the treatment which proposes to overcome or to modify the defect may truly be said to form a subject worthy of notice in a work on Practical Surgery.

The investigation of the early development of the mouth explains the various degrees of extent which congenital fissure of the palate may assume, and such as are constantly found to exist in the new-born infant.

To Mr. Goodsir¹ the profession is indebted for an accurate account of the develop-

¹ *Edinburgh Med. and Surg. Journ.* vol. li. p. 1.

ment of the mouth; and although, in a practical work of this character, it would be intrusive to enter very fully into such a subject, we are compelled to take a cursory view of the changes which occur in the upper jaw *in utero* in order to appreciate the causes of the various deformities which affect it.

In a *fœtus* of about the sixth week examined by Mr. Goodsir, the cavity of the mouth, nares, and pharynx formed one undivided space; the palate was entirely wanting; the outline of the future alveolar ridge was evident. With the particular description of this latter process we need not trouble the reader; but from the inner margin 'a thin semi-transparent membranous fold passed backwards on each side, attached externally to the sides of the capacious bucco-pharyngeal cavity, bounded internally by a free edge, opposed to its fellow of the opposite side, and terminating posteriorly on the lateral walls of the pharynx.

'These folds constituted at this period a partial division of the large common nasal, buccal, and pharyngeal cavity into a superior and inferior compartment.

'The upper wall of this common cavity was smooth and flat posteriorly; but anteriorly it was contracted, and terminated in a longitudinal bar (the future septum nasi), which ran forwards to be attached to the superior surface of a horse-shoe lobe¹ (described) at the median line (in front) and to the other parts in that neighbourhood.

'Under the bar a deep cavity was seen, which communicated with the exterior of the face by two small foramina (the orifices of the nostrils), which constituted at this period the whole external nasal organ.'

In an embryo of about the seventh week, next examined, 'the cleft had slightly diminished, but was still of sufficient width to display the whole of the undivided nasal cavity.'

In an embryo of the second month 'the cleft of the palate had diminished, existing only as a small angular deficiency in the pendulous portion, or soft palate.'

In an embryo of the tenth week the anterior portion of the palate 'had thrown itself into folds; and there was an indistinct uvula.'

The uvula 'was well marked between the eleventh and twelfth weeks.'

If an examination be made of the bones of the palate previous to, or not later than, the sixth month of fetal life, in addition to the median suture between the palate-processes of the superior maxillary bones, a distinct oblique suture will be observed, which starts from the median suture a little behind the alveolar ridge, runs outwards and forwards through the latter, and terminates on its anterior aspect, at the point subsequently marked by the interval between the lateral incisors and canine teeth. So that in fact the under or palate-surface of the superior maxilla is at this period of life (third to fifth month) marked by this suture, as if the bone had been at an earlier period divided into two portions: one, an anterior small 'intermaxillary bone,' or 'os incisivum,' as it is termed, and which carries the incisor teeth; and a posterior, the larger portion, in the alveolar process of which are developed the canine, bicuspid, and molars. This suture disappears, under healthy natural development, soon after, or even before, birth.

The variations met with in the deformities of the palate appear to be distinctly due to an arrest in the development, already described, of the upper jaw and soft palate—an arrest which occurs from some unexplained cause, at an earlier or later period, but probably within the first twelve weeks of fetal life, in accordance with the extent of the deformity. The variations may be thus classed:—

1. The most extensive; a double cleft of the alveolar ridge² with a fissure from each cleft running backwards and inwards, and joining together immediately behind the intermaxillary bone, and being continuous with a median fissure through the entire hard and soft palate.

2. A single cleft of the alveolar ridge on one side or the other of the median line, running back into an entire cleft of the palate.³

¹ This may be taken as the future 'os incisivum' or intermaxillary bone.

² The cleft of the alveolus under such circumstances is often complete throughout on each side from front to back, and from the mouth into the nostril.

³ Instead of the alveolar ridge being cleft, as described, in this variety, there may be only

3. The alveolar ridge entire; the cleft of the palate commencing immediately behind it and complete backwards.

4. The cleft running as far forwards as the middle of the palate-processes of the superior maxillæ, or through the palate-bones only.

5. Fissure of the whole of the soft palate, or only implicating the uvula.

Between the extreme of one and the other every variation of extent may occur.

FIG. 122.—Complete cleft of the Palate with double Hare-lip. (From a preparation in the Museum of St. George's Hospital.)

a the intermaxillary bone, *b*, the septum nasi, *c* the tongue; *d* the cleft into the nasal cavity, *e*, *e*, the parts that divide the upper jaw.

Occasionally, but rarely, a congenital defect is met with in the median line, either as a circular or oblong opening: in front and behind it the palate is closed. These openings most frequently occur in the palate bone; and usually, when such an opening exists, the median line of union is very plainly marked on the under-surface of the soft palate and the uvula by a distinct straight thin cicatrix, showing the union of the sides of the soft palate completed, although the palate bones, in consequence of their defective development, were unable to perfect the naso-oral septum in their immediate neighbourhood.

FIG. 123 Double Hare-lip, showing the intermaxillary bone attached to the septum nasi.

sequence of their defective development, were unable to perfect the naso-oral septum in their immediate neighbourhood.

It will be observed in some cases that the gaps through the alveolar ridge are excessive, *i.e.* complete from mouth to nostril; while in other cases they are but partial. When excessive, and when the fissure is complete through the hard and soft palate, the intermaxillary bone, or 'os incisivum,' becomes often widely separated from the superior maxillæ, and forms a nodule more or less round (the horseshoe lobe of fetal life already described), which is supported by and attached to the anterior inferior termination of the septum nasi. This nodule may be more or less prominent, and is occasionally so much so that it appears simply to be stuck on the tip of the nose. Under these circumstances it is but little covered with skin, which is merely a prolongation from the integument above, and unconnected with the integument of the lip on either side.

a notch, or a large or small foramen through its base. The cleft has been partially closed by growth, or by pressure of the lip.

a notch, or a large or small foramen through its base. The cleft has been partially closed by growth, or by pressure of the lip.

If the nodule be dissected between the sixth and eighth month after birth, in it will be found not only the temporary incisors, but also the germs of the permanent ones; not always the lateral, but invariably those of the central incisors. Occasionally those of the lateral will be found, though they frequently are sacrificed by the freak played by nature in permitting these gaps to occur.¹ Whenever a single fissure occurs through the alveolus, the gap will not be found in the median line, but, as a rule, on one side. We cannot satisfactorily explain this. It may depend on the peculiar conformation of the upper jaw and its early development. We would refer those interested in the subject to the further consideration of Mr. Goodsir's observations.

It is rare indeed that the infant born with extensive cleft palate and alveolus has not also the upper lip notched or fissured opposite to the defect in the bone. Usually, if not invariably, when the cleft of the alveolus is double, the cleft of the lip will correspond; when single, the lip is usually similarly affected. But when the cleft of the alveolus without cleft of the palate occurs, hare lip is not always present.

FIG. 124 Fissure of the Palate in the median line. (From a preparation in the Museum of the Royal College of Surgeons.)

a a the tongue divided in two in order to expose the cleft; *b b*, the larynx similarly divided; *c c*, the two halves of the upper lip and jaw between which is the cleft opening freely into the nasal cavity, the intermaxillary bone being absent.

In complete cleft of the roof the attachment or disposition of the septum nasi varies in different cases. As a rule, the more extensive the gap the greater the deformity. The septum will often be seen, in complete cleft of the palate, to be continuous by its lower border with the margin of one or other of the edges of the cleft; in which case one of the nasal cavities is so far shut off from the mouth, while the other is open to it. In other instances the septum dips down between the nasal fossæ almost as low as the edges of the fissure, and terminates in a free defined border, unconnected with the superior maxillæ; or it will be sometimes seen bent or

¹ When this nodule is very prominent, and appears likely to interfere with the success of an operation for the closure of hare-lip, we would strongly urge the importance of depressing it forcibly rather than removing any portion or the whole of it. It may be forcibly broken and depressed, and made to fit in the gap between the superior maxillæ, where it will almost invariably become firmly fixed, and subsequently have shooting out from it some or all of the incisors. If these be defective, the surface of the bone forms an excellent rest for a plate to carry artificial teeth. If the os incisivum be removed, the superior maxillæ are certain to be more or less drawn together by the action of the upper lip, the latter becomes much flattened, the upper portion of the mouth much narrowed, and the gap in the alveolar ridge never entirely closed.

folded on itself, its edge turned up to one side, with one of its lateral surfaces facing downwards.

These different conditions of the septum have no practical bearing on the subsequent treatment of the case. Rokitsansky alludes to fissures of the palate caused by the absence of the os incisivum, and attended by fissure of the upper lip *in the median line*; ¹ but he does not state that he had met with an example of this rare deformity. Sir Wm. Fergusson, ² in alluding to the occurrence of cleft in the lip, says: 'Doubtless it has been named hare-lip from a certain resemblance to the fissure in the upper lip of the hare; but in the human subject it differs in this peculiar feature, that it never is in the mesial line, as it always is in the hare.'

Rokitsansky only alludes to the occurrence of the fissure in the median line, but gives no details of any peculiarities which might be supposed to accompany such a defect. Sir W. Fergusson had apparently not met with a case; and the deformity is no doubt most rare. But a specimen such as Rokitsansky refers to—the result of absence of the os incisivum and fissure in the median line of the upper lip—may be seen in the Museum of the Royal College of Surgeons in London. In this preparation (of which no history is recorded) the fissure of the upper lip is in the mesial line, the result of a great gap, as if a large portion of the middle of the lip were destroyed; the os incisivum is altogether deficient, no vestige of it being present; and the cleft of the hard and soft palate is complete.

But there is this additional interesting feature in this remarkable specimen; the anterior nasal apertures are wanting. The explanation of this latter defect appears to be simple. The os incisivum being absent, the septum nasi has nothing to attach itself to in front and below. The anterior orifices of the nostrils are therefore defective; the apex of the nose does not project; the alæ are flattened; and as the *entire* floor of the nares is deficient, and the anterior lower portion of the septum terminates by a free edge, the would-be anterior orifices of the nostrils are merged in the median gap of the lip, alveolar ridge, and mouth. Probably the child was still-born, or died soon after birth.

We do not attempt to enter into an explanation of the causes of cleft palate. Observation has not thrown any light on what may reasonably be considered merely an arrest of development at some period of fetal life prior to the fourth month. Thus much, however, we may state, that in the isolation of the os incisivum from the superior maxilla we find an approach to a somewhat similar arrangement in the teeth of the upper jaws of certain animals, in whom the incisors are separated by a distinct interval or gap from the bicuspid or lateral teeth.

Cleft palate and cleft lip are frequently found to affect more than one member in a family; but we cannot state that congenital cleft of the mouth or lip is a common occurrence, as a result of hereditary transmission. It is rare to observe both the parent and offspring affected on either side, although brothers and sisters of the same family constantly present different conditions of the deformity. ³

Practically, the more extensive the cleft in the palate, the more upright will be the surfaces forming the sides of the gap. Usually the cleft in the palate is narrower in front, and widens towards the velum. But much variety will be found if a large number of cases are compared with each other. In some the gap is wide; in others, though complete from alveolus to uvula, the gap will be narrow. When the cleft is only partial, the less it encroaches upon the hard palate, the more natural will be the arch of the roof in front; and the sides of the partial cleft will also somewhat partake of the natural curve of the arch rather than run upwards, as is almost always the case when the cleft is considerable, or extends entirely through the palate and alveolus. When restricted to a small portion of the palate-bone and the soft palate, it by no means follows that the cleft is equally narrow in proportion; on the contrary, it will be frequently found that these partial clefts are very broad; so much so in some instances that the palate processes of the palate-bones and the sides of the bifid soft

¹ Rokitsansky, *Pathological Anatomy*, vol. ii. p. 3.

² *Practical Surgery*, p. 584.

³ How far civilisation or crowded populations may influence congenital deficiencies in the human subject is a question to be hereafter worked out; but it is a curious fact that most of the young of the lions caged in the Zoological Gardens of London are born with defective palates, and consequently die soon after birth. As far as our limited means have enabled us to ascertain, it appears that it is not usual for the lion family, in a state of confinement, to have their young similarly affected, but that this congenital defect is restricted to the lions kept in the Regent's Park, as if some local influence were instrumental to this end.

palate appear to be almost wanting. These partial clefts in some few instances are so broad that operative interference is unadvisable, as there would not be, even of the soft palate, sufficient tissue to allow of the edges meeting, or being approximated without undue tension.

The primary effects of cleft palate, when extensive, are sufficient to create much necessary alarm for the safety of the infant's life. If hare-lip exist, with double or single cleft of the alveolus, and a broad cleft of the roof, unless the infant be supplied plentifully with its mother's milk from the first, it will probably soon sink from exhaustion. It is very difficult in such cases to introduce a sufficient quantity of milk into the stomach, to insure an amount of nutrition equal to the maintenance of life. The mother's milk is the only food that should be given for the first six or eight weeks. In all cases of cleft palate, the infant is unable to suck the nipple; for as the naso-buccal septum is wanting, the child cannot create with its tongue a vacuum in the mouth, and is therefore unable to draw milk from the ducts of the mammary gland. There is no alternative but to hand-feed such an infant. It will be found most convenient to place the infant in the upright posture while it is fed; this position allows the fluid nourishment to flow backwards and downwards into the pharynx, instead of running into the nares and out of the nasal apertures, as occurs when the child is fed lying on its back.

After a few weeks of this careful nursing, the child will begin to take its food with greater facility; and as it grows older, with a freedom which is somewhat surprising when the amount of defect in the palate is considered. But as these children have often a very great struggle for life in the earlier weeks, we repeat that *breast-milk should be alone given*. The milk should be drawn from the mother or nurse and given with a bottle, to which a smooth flat ivory pipe is attached; its orifice should be small; and the flow of the milk through it so managed that suction is not requisite, but at the same time the current be gentle, and easily regulated by the inclination of the bottle in the nurse's hand, or a small piece of sponge dipped in the milk and then placed in the mouth will often be found to answer equally well, but of course the process requires to be repeated as often as the milk is sucked out of the sponge; great care is requisite and judgment necessary in supplying sufficient nourishment to the infant, and for this purpose an experienced nurse is most desirable. So much as regards the early nursing of a child born with cleft palate. The question now to be considered is, the surgical interference by which the condition of the mouth may be improved, and at what age such treatment may be safely and successfully adopted. In the first edition of this work, we stated our opinion that it was not desirable to attempt to close the fissure of the palate, by operation, during infancy, and that such treatment were better deferred to a later period, when the patient was old enough to judge for himself whether he would prefer to wear an artificial palate for life or have the fissure permanently closed, and was moreover of an age to submit to an operation without the aid of chloroform.

Since that time, however, the experience of others, as well as our own, has induced us to materially alter our opinions and practice in this respect.

Mr. Thomas Smith, of St. Bartholomew's Hospital,¹ was, we believe, the first to introduce the use of chloroform in operations on the palate in children; under its administration clefts of the palate may be readily and successfully operated on in childhood at a very early age. Prior to the publication of his observations, other surgeons had succeeded in closing such clefts in young children;² but Mr. Smith, in addition to the information given to the profession, that chloroform can be satisfactorily employed in such operations with considerable advantage to the surgeon, has also aided still further to perfect the steps of the operation, and render it one of comparative ease and simplicity, by the introduction of his ingenious gag for keeping the jaws asunder while an operation is being proceeded with.

¹ *Trans. Med.-Chir. Soc.* vol. li. p. 70.

² In one case operated on by M. Billroth of Zürich, a cleft extending from the lip to the uvula was closed by successive operations before the age of twelve months. See Billroth, in *Langenbeck's Archiv*, vol. i. p. 657.

The real object of the operation of closing the cleft in the palate is to enable the patient to articulate hereafter plainly and intelligibly—not to enable the child to take food. An infant with extensive cleft, when first born, has often some difficulty in taking sufficient to satisfy its wants, or to nourish it, as it would be nourished were its palate perfect; but usually this difficulty is overcome in a few days, and if proper care be taken the infant usually thrives. An operation at this period is therefore not requisite, nor is it desirable: the loss of blood the infant would sustain in such an operation would be attended by great risk to life; the tumefaction and tenderness of the mouth subsequent to the operation would be sufficient to interfere greatly with its taking a proper amount of nourishment; and both the loss of blood and the insufficient quantity of food might materially interfere with the union of the flaps, even supposing the infant survived under such circumstances. A very slight loss of blood may prove fatal in the very young, especially in one of a puny delicate nature, such as children with cleft palates often are; but the loss of blood in an operation for cleft palate is often severe, more especially when the hard palate is dealt with: great risk would therefore be run by early resort to this operation, and fatal results would inevitably occur in many cases.

Dr. Ehrman,¹ in a very interesting and complete memoir on the subject of cleft palate, mentions the death of four cases, in infants in whom the operation on the hard and soft palate had been attempted—one of four days old, one of five days, and two of two months each. As a child does not commence to articulate, as a rule, before twelve months old, nor to pronounce many words before two years of age, there is no imperative haste for the adoption of the operation before that age, nor is there any advantage to be gained by its earlier completion. The reasons are strong against its performance prior to this period of life; some few months later the child is in a much more favourable condition to undergo the operation, and less liable to succumb from the effects of loss of blood. Under all these circumstances it is safer, and ultimately equally efficacious for the improvement of the articulation, to defer all operative interference until the child is two or three years of age. With the use of the gag and the administration of chloroform, the operation may then be undertaken without hesitation, can be readily performed, and in a large majority of cases will be successful.

As the most simple form of cleft is that confined to the velum or soft portion, we propose to consider, first, the method to be adopted to close it, irrespective of any extension of the fissure into the hard palate.

Should the uvula alone be bifid, very little is requisite to secure union of its opposed edges; and indeed, if the voice be not affected, nor the cleft detected by any peculiarity in the articulation, it is better not to meddle with the fissure. Cleft of the uvula, however, does usually affect articulation. The surgeon need have no hesitation in undertaking the operation. The opposed edges of the bifid uvula should be pared, care being taken to carry the incisions on either side a little way into the soft substance above, so that they meet in the median line in front of the commencement of the cleft; care must also be taken that the mucous membrane at the edges is sufficiently removed to ensure two raw surfaces being adapted to each other. The surgeon should first seize one point of the bifid uvula with a pair of long spring forceps, and draw it forwards, transfix it near its inner border with a narrow sharp knife on a long handle, and freely cut upwards and downwards, in order to remove the mucous membrane along the whole of its inner margin. A similar proceeding on the opposite side completes the use of the knife. Two or three sutures of horsehair or fine silk will be sufficient to approximate the edges and keep them in place.

Whether the fissure implicates merely the uvula, whether it be confined to the whole extent of the soft palate, or whether it affects the whole of the hard and soft it is best, on the part of the operator, to commence by paring the edges of the cleft in its entire extent before proceeding to any other step necessary in the completion of the operation. Great care is requisite to free the edges sufficiently of mucous membrane; it is better to remove a little more than necessary rather than an insufficient

¹ *Etude sur l'Uranoplastie.* Paris, 1860.

surface. The success of an operation will not be interfered with by attention to this precaution, whereas the result will surely be to some extent unsatisfactory if the latter condition obtains.

In the most extensive fissures, if the edges are pared before the parts are disturbed, the operator is enabled to appreciate how far he may have succeeded in sufficiently exposing the edges; the bleeding is but trifling, and, as soon as it ceases, the cut surfaces can be cleansed with a sponge, and careful examination made in order to ascertain if more or less of the mucous edge should be removed. If the edges be not pared until after the soft tissues have been separated from the bone, it is much more difficult to ascertain whether sufficient mucous surface has been removed to ensure two perfectly raw edges being brought together; a very small patch of mucous membrane intervening between the edges of the flaps will, to the extent of its surface, or perhaps even to a greater extent, interfere with union of the most accurately adapted edges of a fissure by sutures.

When a cleft extends forwards through the whole of the velum, or even to a slight extent into the palate-bones, the operation is rather more complicated than that above described; and, though not beset with difficulties, requires a careful examination into the anatomy of the soft palate, and some little familiarity with the operation, before the surgeon can be confident of obtaining that success which should usually follow attempts to close a cleft palate by surgical interference.

If a fissure of the soft palate be carefully examined, and with the mouth open the patient make an attempt to swallow, the action of the muscles of the pharynx and tongue is such that the edges of the fissures are approximated by the action of the superior constrictors; the extremities of the bifid uvula touch, and often the gap is for an instant closed to one-third or one-half of its extent; but immediately afterwards the sections of the soft palate are drawn back to the walls of the fauces; and often the whole of the soft palate itself is so closely contracted into the side of the fauces, that a superficial observer might conclude, in some instances, that no soft palate existed. This latter effect is the result of the combined actions of the levator and tensor palati muscles contracting towards their attached extremities, and thus drawing up the sections of the velum. So that every attempt to bring the edges of the fissure together would be opposed by these muscles on either side pulling away from the median line, and consequently drawing directly from the line at which the edges of the fissure should meet to ensure union.

That the edges of a wound should meet without any traction on its margin by sutures is a fundamental rule which applies generally to all plastic operations; but especially is it absolute in any operation to close a fissure of the palate, whether in the hard or soft portion.

Union by first intention is equally essential to the success of an operation. If the approximated edges of the fissure do not unite at once after being brought together and there retained by sutures, the operation will fail for the time. No benefit or obliteration of the cleft will be gained by the process of healing by granulation. It is therefore most important that the condition of the patient should be that of perfect health. Nor can a surgeon be too careful in satisfying himself on this point before he decides the day for the operation. A loaded tongue, a catarrh, or a pustule on the skin—if any one of these be present it indicates, as a rule, a condition sure to spoil the best effects of the most skilful operator. In fact, conditions trivial in themselves, and perhaps of but little import in the balance which would influence other operations, should, in cases of cleft palate, be decisive against operative interference until a clean bill of health can be written for the patient.

The particulars of the following case illustrate the importance of such precautions. The author operated for fissure of the soft palate in a girl ten years of age, and apparently in perfect health. The operation was most satisfactory in its immediate results; the gap being entirely closed. The parts looked perfectly united on the second day. On the third day the little patient showed symptoms of scarlet fever, and in a few days after the line of union had entirely given way. The parents had brought this child from the country a few days previous to the operation, but had left another at

home recovering from the effects of scarlet fever, and of these circumstances not a word was mentioned until after the appearance of the eruption subsequent to the operation.

In an operation requisite to close the soft palate, the division of its muscles is, in one way or another, absolutely necessary, to allow, 1st, the edges of the cleft to be brought easily together, 2nd, to enable them to be kept in apposition without any strain on the sutures. This latter condition is essential to secure union and secure success.

The late Sir W. Fergusson was the first to propose and practise this division of the muscles of the soft palate before attempting to bring together the pared edges of a cleft.¹ Prior to the adoption of this method of operating, attempts to close a cleft in the soft palate had been attended by little, if any, success; and but very few surgeons ventured to undertake this operation. The action of the undivided muscles of the soft palate frustrated the most skilful attempts to overcome this deformity. The author may state that, when he commenced to deal with this class of cases, he had never seen such an operation as an attempt to close the cleft undertaken in St. George's Hospital. Very great credit is therefore due to Fergusson for having seized on the causes of difficulty and obstruction which rendered futile all previous attempts to remedy the deformity of a fissured palate, and for establishing the simple rule by which it could be successfully and effectually remedied. His work, indeed, in this respect was not only the foundation of the success of this operation, but of the subsequent improvements which have gradually followed, and rendered this once formidable and often unsuccessful undertaking a matter as simple as it is generally satisfactory.

The name of William Fergusson must ever be associated with this first grand improvement in the operation of 'staphylorhaphy'; he hit accurately the exact difficulty after careful observation and dissection, and applied the result of his investigations with dexterous skill and success to the realisation of a most valuable and practical result. The author considers it only a duty to speak thus of one who did much for the advancement of operative surgery, and whose kindly nature attached him to all who had the privilege of his friendship. Fergusson's method was to divide these muscles with a knife bent at a right angle. This shaped knife enabled him to cut on the posterior surface of each flap of the bifid palate, and so divide the muscles from behind. A more simple and equally satisfactory method of securing the division of these muscles was subsequently recommended and practised by the author. He found that the levator muscle could be readily divided by cutting through the soft palate at each side, and moreover that the lateral incisions requisite for this purpose assisted in lessening tension when the sutures had been secured.

In order thus to effect the division of the muscles alluded to, the point of the uvula should be caught in the long spring forceps usually employed in operations for cleft palate, and drawn gently forwards and somewhat to the opposite side. A thin, narrow, sharp-pointed knife fixed in a long handle is then to be introduced into the soft palate close to the hamular process, a little in front and to its inner side. This process can be distinctly felt in the substance of the soft palate, internal and very little posterior to the last molar tooth. Running the knife upwards and backwards and somewhat inwards, the point should at last be seen in the gap, having been passed through the entire thickness of the soft palate, and having cut, if not wholly, at any rate partially, through the tendon of the tensor palati; the blade of the knife should now lie above most of the fibres of the levator. If the handle of the knife be next raised, the point will become depressed, and if the blade be then drawn forward, while at the same time it is ~~made~~ to cut downwards, it will travel through a considerable section of a circle on the posterior surface of the palate, and ensure the division of the greater portion of the levator palati. As the knife-blade travels downwards, the tension of the palate gives way, and often the division of the muscle may be felt to be suddenly effected. Provided the muscles be sufficiently divided on each side, as soon as the knife is withdrawn it will be found that all movements of the palate have ceased—it

¹ *Med.-Chir. Trans.* 1845.

has become pendulous and flaccid. Should, however, any resistance or action of the muscles be still observed if touched or pulled by forceps, the knife should be again introduced and the fibres a little more freely divided in a downward direction.

So far we have only referred to the treatment of fissure confined to the soft palate, but implicating it in its entire extent. It will be frequently observed, however, in some of the latter cases that there is difficulty in drawing the edges of the fissure perfectly together at the anterior extremity—viz. where the soft joins the hard palate. Here the mucous surface of the bone, as well as the substance of the soft palate, is sometimes very thin, and perhaps the fissure extends forwards to implicate just in the slightest degree the posterior edge of the palate-bones.

Whenever this condition is met with, when any difficulty arises in satisfactorily approximating the edges at this part, it is best to separate the soft tissues of the hard palate from the bone. First, perhaps, it may be requisite to extend the lateral incision somewhat forwards; then the soft tissues must be separated by commencing at the lateral incision and working inwards towards the fissure, and until this edge is reached. This can be best done by a slightly curved steel instrument with a somewhat blunt-ended blade fixed to a handle, and known as the separator.

The soft tissues being liberated between the lateral incision and fissure, a pair of curved scissors should be introduced through the lateral opening, and the attachments of the soft palate to the posterior edge of the palate-bone between the incision and cleft entirely freed on each side.

The flaps being perfectly flaccid, and their edges having been previously carefully and sufficiently pared, the approximation and perfect adaptation of the latter to each other must now be completed by the introduction and security of sutures. Very fine silk or thread or horsehair, according to the fancy of the operator, is preferable to silver-wire sutures in cases in which the soft palate is concerned. For the introduction of the suture it is best to use a needle bent at a right angle about an inch from its pointed extremity, and fixed to a long handle. This shaped needle can be passed very readily from one through to the other flap, and made to penetrate the latter at any point desirable, and the suture carried right across from one flap to the other without any change or stop.

When about to pass the first suture the surgeon should steady the flap by securing the end of the uvula with the long forceps; then, with slight traction, he can render the flap somewhat tense, and thus more readily secure the passage of the needle.

The needle having been made to perforate both flaps, and its point being now clear in front, the loop of the suture is to be secured by forceps or hook, or caught up by an instrument used especially for this purpose, and which consists of a narrow blunt blade, notched sufficiently deeply at one edge near its end to enable it to catch the suture in the notch as the instrument is drawn over it. One end of the ligature being thus secured on one side, the needle is to be withdrawn from the flaps, carrying with it the other end of the suture. As soon as the needle itself has been disengaged from the latter the two ends should be loosely looped together, and then given over to the hand of an assistant to hold outside the mouth.

The requisite number of sutures having been introduced and similarly treated, the surgeon should commence to tie each separately, from below upwards—carefully, so as to adapt the edges evenly to each other, and not too tightly, that something be allowed for subsequent swelling of the soft tissues. If the sutures be tightly drawn, they will most certainly cut themselves out by producing ulceration of the part on which they press.

A slip knot, to bring the edges together, and a second knot over that, are sufficient to secure each suture, and maintain apposition until union is safe. The ends of the sutures should not be cut off very close to the knots, for if of hair they are apt to slip, or if of silk or thread, when thoroughly sodden with saliva the knots are almost certain to become loosened, or even to become untied in a very short time, and much too soon for safety.

Great care is requisite to free the edges sufficiently of their mucous covering; it is better to remove a little more than necessary than an insufficient quantity, for the

success of the operation is not interfered with in the former case, whereas the operation will most certainly fail to some extent in the latter condition.

Mr. T. Smith's method of operating is, first, to pare the edges of the fissure from below upwards, then to pass the sutures, and lastly, 'to draw up the palate with all the sutures in one hand, and with the palate on the stretch to divide, if necessary, the palato-pharyngeus, and subsequently the levator palati; if the palate will not come easily together, two lateral oblique cuts may be made, one on either side above the highest suture, separating the soft from the margin of the hard palate to a small extent.¹

The operation for closing the hard palate has now to be considered; it must, however, be borne in mind that this the major involves the minor operation—*i.e.* that in dealing with fissures of the hard palate the closure of the soft palate must be included. The defect in the bone is never seen without complete fissure backwards, throughout the entire soft palate right to the tip of the uvula.

Complete fissure of the palate, or one extending to, or near, the alveolar ridge, may generally be closed without difficulty. Although Fergusson mastered the difficulties of closing fissure of the soft palate, the late Mr. Avery, surgeon of Charing Cross Hospital, was the first in this country to deal successfully with fissure of the hard palate. It was under his able teaching that the author gained his early experience, and was subsequently enabled to bring the subject to the notice of the profession, in a paper published in the 'Transactions of the Royal Medico-Chirurgical Society.'² Some years previous to his death, Fergusson proposed a method of closing the hard palate by cutting through, on each side, the fissured processes of the superior maxillary and palate-bones close to their junction with the alveolar processes, and then by bending these down, without disturbing the soft tissue attached to them, made their edges meet in the median line. This, of course, only applied to the fissure in the hard palate, the soft palate being closed in the manner already discussed. This operation was successfully adopted by him in some few cases; but it did not gain favour with surgeons familiar with operations on the palate. It was a severe operation, and rendered quite unnecessary by that now usually adopted of separating the soft tissues from the bone.

The operation of closing a cleft in the hard and soft palate may be undertaken without hesitation in children after two and a half to three years of age; and may without risk or difficulty be completed in one operation, either in children or adults.

The surgeon having satisfied himself that the patient to be operated on is in a thoroughly good condition of health, will be wise to secure the services of some one accustomed to the administration of chloroform or ether in similar cases. The administration of chloroform is apparently safer in children than in adults; it possesses one advantage over ether in this operation, inasmuch as it produces less salivation and frothing of saliva during its performance. Still it has to be used with caution; and some little experience on the part of the administrator will prove a vast comfort and assistance to the operator. The anæsthetic has to be administered at intervals. When the patient is fully under its influence the operation is commenced by the edges of the fissure being pared; then bleeding from the cut surfaces occasion some delay in the proceeding; the patient now partially recovers, and again the anæsthetic has to be administered. These interruptions, frequently repeated, are well managed by one thoroughly accustomed to its administration, and advantage taken of the right moment to apply it. Economy of time is the result, whereas a raw hand may greatly add to the surgeon's work, and would probably fail to keep the patient sufficiently at rest without some risk of endangering life.

If the patient be a child, it is best to have it placed on a rather high narrow table with head only slightly raised on a pillow. The arms had best be secured to the sides, and advantage will be gained if the legs are tied together and fixed by bandage or strapped to the table.

¹ *Trans. Med.-Chir. Soc.* vol. lii. p. 84.

² *Ibid.* vol. xxxix. p. 71.

The patient being sufficiently under the influence of an anæsthetic, the gag for keeping the jaws asunder has next to be adjusted, and the head to be held steady by a nurse or assistant during the operation. The edges of the cleft to their entire extent should first be pared. This can best be done with a fine, short-bladed, and thin double-edged knife on a long handle. The double-edged blade has a great advantage in this operation, as it enables the surgeon to cut either forwards or backwards without turning the knife, and this is economy of time—a matter of some importance, as the surgeon can only act while the condition of insensibility to pain lasts.

Lateral incisions have next to be made through the soft tissue of the hard palate, and are to be carried back a short distance, so as to enable the surgeon to cut through a portion of the soft palate. In complete fissure of bone and alveolus, the incisions should be close to, and parallel with, the alveolar ridge on each side, and should extend as far forwards as the canine tooth, and backwards a little beyond the last molar. The extent, however, of the lateral incision in less extensive cases must of course be somewhat regulated by the extent of the cleft in the hard palate. In young children it is best not to extend the incisions more than is absolutely requisite to enable the operator subsequently to separate the soft tissues from the bone. If recklessly prolonged, the tissue forming the flap may slough from want of nutrition, and such a result will surely spoil the operation and terminate in disappointment. The soft tissue which lies between the incisions and the cleft must next be separated from the bone by means of the instrument already referred to as the separator, and this separation should be commenced from without, and continued inwards until the free edge of the gap is reached throughout the whole extent of the hard palate on each side. This separation of the flaps from the bone can be readily and effectually accomplished, with little risk of bruising or cutting through them: a matter of great moment for the ultimate success of the operation, for should the flaps be much bruised or torn in the process of their separation from the bone, ulceration or sloughing is apt to supervene and materially interfere with the union requisite to the success of the operation.

The flap detached from the bone should consist of all the soft tissues covering the latter—mucous membrane, areolar tissue, and periosteum. If the soft tissues are separated from the bone in the manner recommended, on the dead body, it will be found difficult (and we conjecture equally difficult in the living subject) to peel off the thick mucous membrane without the subjacent periosteum. The operation which Professor Langenbeck proposed, and to which he gave the name of 'the operation by muco-periosteal flaps,' appears to be identical with that introduced by Mr. Avery.¹

When the soft tissues have been effectually separated from the bone, the flaps should fall inwards and downwards and meet in the median line, without the slightest traction being requisite. If the edges do not readily touch, the flaps have not been sufficiently detached from the bone on one side or the other; and care must be taken to ascertain the point which prevents their sufficient descent, and this should be freely liberated; nothing must be allowed to interfere with the free approximation of the edges.

The surgeon will find it an advantage to liberate behind the flaps any attachment of the soft tissues to the posterior borders of the palate-bones. This is best done by introducing a pair of curved scissors through the lateral incisions, and cutting inwards behind the flaps until the edge of the cleft is reached. What is divided by this latter proceeding is the attachment of the upper or posterior surface of mucous membrane and tissues of the soft palate. The latter is thus fully liberated, and offers no resistance by contraction or movement to the approximation of its edges.

Mr. Annandale² reports that he succeeded in closing fissures of the hard and soft

¹ See Prof. Langenbeck's treatise entitled *Weitere Erfahrungen im Gebiete der Uranoplastik mittelst Ablösung des muco-periostealen Gaumenerübzuges*. Berlin, 1863.

² *Edin. Med. Journ.* 1865, vol. x. p. 621.

palate by the adoption of lateral incisions merely, without division of the muscles of the velum either in the manner adopted by the author or that which had long been recommended and practised by Fergusson; but Mr. Annandale carried the lateral incisions as far back as the last molar tooth. The results were perfectly satisfactory in the two cases related by him.

When the fissure is extensive, and more or less complete, the free separation of the soft tissues from the bone is amply sufficient to allow the margins of the flap to meet easily in the median line; occasionally they will overlap, in which case the edges require to be carefully adjusted. They should be examined, and, if found to be a little ragged, they should be made even; the possibility of any mucous surface becoming insinuated between them will thus be avoided, and the contact of two entire and fresh raw surfaces ensured. Fine silver sutures are generally recommended, and used to secure the edges of the soft tissues of the hard palate.

Mr. Annandale used silver wire with perfect success for closure of both hard and soft palate; but we think, as a rule, it will be found most convenient to use thread or horsehair sutures, with the needle bent at a right angle for the soft palate; while, on the other hand, it will be found most easy to pass a silver wire suture in a bent tubular needle through the soft tissues of the hard palate; and this in consequence of the arch of the latter being an impediment to the passage of any needle bent at a right angle. The latter can only be conveniently used for passing the more flexible sutures of silk, thread, or hair, while the curved tubular needle can alone be used with a metal suture.

A tubular needle, especially constructed for this purpose (introduced, we believe, by Mr. T. Smith), is the one we recommend. It is sufficiently curved to enable the surgeon to pass it readily through the flap to his right, across the fissure, and then from behind to penetrate the flap to his left until he can see the point of the needle projecting fairly in front of the mucous membrane of the latter. A long handle is attached to the needle, and has a small wheel and reel attached to it. On the latter is coiled silver wire, the free end of which is carried up and through the tube in the needle to near its point. When the wheel is rotated by the action of a finger or thumb, the wire is drawn on and pushed upwards as it uncoils from the reel until sufficient is apparent projecting from the point of the needle to enable the surgeon to seize it with a pair of forceps, and draw it out as far as may be necessary to allow of its being held with the fingers of the operator. This being accomplished the needle is to be withdrawn, leaving a suture lying across the cleft and through each flap. The wire is now to be cut off near the point of the needle, after allowing such length to the ends of the suture that they may easily be held outside the mouth, the points are then to be lightly twisted together and given over to the care of an assistant. As soon as a sufficient number of sutures have been passed, each should be separately secured by its respective ends being twisted together. A very effective little instrument may be used for this purpose, and with it the suture can be tightened up to whatever extent the operator may consider desirable. When sufficiently tightened, the ends of each suture should be cut off near the twist. With silver-wire sutures there need be no fear that the knot or twist will give way, provided it be properly and sufficiently secured; whereas the presence of a long end of a sharp wire in the mouth may prove a source of annoyance and trouble, especially in the case of a young child.

The use of silver wire for securing the apposition of the edges of the flaps of the hard palate has the advantage that it may be retained as long as the surgeon should consider desirable without producing local irritation or mischief. The removal of the suture must of course depend on the condition of union. As a rule the author is an advocate for their early removal, if justified by the appearance of the line of union. In children it is best to remove them under the influence of chloroform.

When a fissure of the hard palate is complete, or nearly so, the sides of it will be found to approach more or less to the perpendicular in their direction, as shown in figs. 125, 126. The result is, fortunately, that when the soft tissues are sufficiently detached from the bone, the flaps fall inwards and downwards, and readily meet in

the median line ; there is always ample material to permit of their arching over the defective roof when they are once liberated from the bone.

But when the fissure in the bone is confined to the posterior half, the portion of the palate in front of the fissure, and whatever portions of the palatal processes exist at the sides, will be observed to approach, in curve, the arch of a perfect palate as

FIG 125.—Drawing from a model of a complete Cleft of the Palate (St George's Hospital Museum)

FIG 126.—The same model cut in two to show the perpendicular direction of the sides of the gap

seen in figs 127, 128, taken from the model of a cleft of this kind, the bony fissure will often be broad, and rounded in front, and the membrane covering the bones very thin. In such cases, if the soft tissues are merely detached from the bone at the sides and front of the fissure, there is not much spare surface to close the gap, consequently the edges of the flaps do not meet in the median line so readily as

FIG 127. Drawing from a model of a partial Fissure of the Palate (St George's Hospital Museum)

FIG 128.—The same model divided, showing the much more horizontal direction of the sides of the gap.

occurs when the tissues are detached from the more upright sides of more complete fissures. Often, however, a fissure of the posterior half is narrow, pointed in front, and its sides covered with thick velvety mucous membrane. Under such circumstances little difficulty is experienced in getting the edges together.

When cases with broad fissures of the posterior half of the hard palate are operated on, it is almost impossible to approximate the entire length of the edges. The lateral incision may be free, and the separation of the soft tissues from the bone perfect, but still without *pulling* the edges together by sutures we cannot secure their meeting. But as sure as any force or pressure is requisite to *draw* these edges together, so sure is the suture to cut its way through a part, if not the whole, of the flap, and union does not follow. *Sutures should hold, not draw, parts together, if union is to follow.* Sometimes it will be found desirable to plug the incisions with a little soft cotton; this helps to push the flaps towards the median line, and takes off some of the traction of the sutures. This traction had better be avoided and the suture corresponding to this part only slightly drawn, so as to support the flaps rather than pull them together.

Such cases as the latter are most unsatisfactory to deal with. A subsequent operation may be attempted, and even repeated, if considered likely to be beneficial; but if the gap left should appear too large to be benefited by any subsequent operative interference, it would be better that the patient should use an artificial palate—at any rate, until the full benefit of the first operation can be estimated.

It not unfrequently happens that, under the most favourable circumstances, and with the greatest care on the part of the operator, a small aperture, or fissure enough to admit the flat end of a probe, will remain at the meeting-point of the hard and soft palate. Under such circumstances a metal plate should be worn for a period, *over the opening*, to prevent the percolation of saliva and other fluids through it. Under such treatment it has a tendency to close. But if any substance, such as a plug, &c., be made to project continually *into the opening*, and thus press on its margins, it will invariably and gradually increase in diameter; in time the plug will become loosely held and useless, to be replaced by a larger one, and this will be followed by progressive increase in the size of the aperture.¹

If it should happen that a patient, with hare lip and cleft alveolus and palate, should not have had the lip operated on in childhood, it will in all probability be found that the cleft of the alveolus is considerable—sometimes sufficient to allow the point of the finger to be passed through it from nostril to mouth. Under such circumstances the first cure should be to operate on the lip. Subsequent to the healing of the lip, the action of its muscles in a very short time will so have approximated the edges of the separated alveolar ridge as to make them touch, though, in consequence of the interposition of the mucous surfaces, the chink between them never appears to be obliterated unless the mucous membrane be removed.

Occasionally small orifices are met with in the palate, either congenital, or more frequently the result of some cachectic or syphilitic condition, terminating in necrosis and destruction of a portion of the bony palate. In either condition, some little difficulty will usually be encountered in attempts to close such orifices. In all instances lateral incisions are requisite; and a repetition of the operation may be necessary even more than once before entire closure be effected. But, under any circumstances, should the opening be not ultimately filled up, it will generally be greatly reduced; so that the patient will be enabled, with the aid of an artificial palate, to secure himself from the discomforts attendant on a perforation of the roof.

Orifices through the soft palate are usually, if not always, the result of ulcerative

¹ The author would not be doing justice to the memory of the late Mr. Avery, in omitting to mention that he was the first surgeon in this country to close entirely a complete cleft of the palate. Since then the operation has been frequently and successfully performed in England and on the Continent. To Dr. Warren, of Boston in North America, the profession is chiefly indebted for having advocated the closure of the hard palate by operation. In the *New England Medical and Surgical Journal*, and also in the *American Journal of Medical Sciences*, as early as the year 1843 (also in 1848), Dr. Warren gave the result of his operations on fissures of the hard as well as the soft palate. Although complete closure does not appear to have been effected in any of these cases by one operation (which Dr. Warren appears always to have had recourse to, to close both hard and soft palate), yet his success by subsequent treatment in the management of these cases marks him as one of the pioneers in the advancement of this department of surgery.

action. Generally they close after a time, without the assistance of an operation. An opening, the result of strumous ulceration of the soft palate, and of the size of a six-penny-piece, in a patient under the care of the author, contracted and closed entirely, after cicatrisation of its margins had occurred, without operation or any surgical treatment. When, however, such an opening ceases to contract, and holds out no prospect of natural obliteration, but promises to be permanently patulous, its edges should be pared, lateral incisions made, and the margins brought together and retained in apposition by sutures.

The amount of blood lost during the performance of an operation on the palate will vary to a very great extent in different cases; but usually much more is lost in the process of detaching the tissues from the bone, than in the operation on the soft palate. The anterior and posterior palatine vessels sometimes bleed profusely after division; so much so, that occasionally it is necessary to make pressure for a few moments or more, with the finger; especially on the anterior, which generally bleeds more profusely than the posterior vessels. Iced or cold water should be used frequently, to syringe the mouth during the operation, when hæmorrhage is free. The loss of blood in no one operation, under the experience of the author, has been attended by evil consequences. Women are often apt to faint from a small loss of blood, but as the operation should be performed under the influence of an anæsthetic, such a result is less liable to occur than when pain is added to a loss of blood.

The patient should be *plentifully supplied with nutritious fluid and soft food* for some days after the operation: strong beef tea, bread and milk, tea with half milk or cream, strong soup, and beer or wine, according to the age of the patient. In children milk with bread thoroughly softened and pulped in it is sufficient for many days; or, better still, milk alone. From the first hour after the operation, strict attention to this rule forms an important element in the satisfactory union of the flaps.

It might be supposed by some, who have not experience in this class of cases, that, after an operation on the soft palate, the effort of swallowing would be an effective impediment to union, in consequence of the action of the muscles of the palate; but it must be borne in mind, in the first place, that, prior to an operation, the palate-muscles have no power in themselves to assist in the act of deglutition. In the second place, the divided, and to an extent crippled, muscles of the palate are naturally passive in deglutition until union and reparation are established and complete. So, in practice, it is found that, as long as a patient is restricted to soft or fluid articles of nutriment, union is not retarded by the mechanical action of deglutition, however often he may be fed in the day. But if all diet be withheld, the patient's strength, already lessened by loss of blood, becomes lowered to such an extent that reparation is rendered doubtful, and union of the parts is retarded, if not ultimately prevented. All solid food should be avoided for a week or ten days.

The sutures should not be permitted to remain in the flaps many days. Usually, in the soft palate, the two lower ones should be removed on the second day; and if there be four sutures, one of the two latter should be taken away each succeeding day: that which is highest to be last removed. It has been supposed desirable to retain the sutures in the flaps for a longer period; but in each fresh case that comes under our notice, it becomes more evident, that if union is satisfactorily established, the retention of the sutures beyond the third or fourth day only tends to render it less effective: and if the condition of the edges of the approximated flaps is not satisfactory, and their union is not firm, the presence of the sutures will aggravate rather than diminish the evil. These observations do not apply to silver sutures; such sutures may be retained indefinitely without prejudice or irritation to the parts involved.

The patient should not be allowed to speak until union is complete, and the sutures are removed. He should be provided with materials for writing all his wants; a small slate and pencil will be found most convenient for such a purpose. In the case of a child, it is well that the nurse should endeavour to impress on it the necessity of silence, and use every possible means to amuse it. We have found nurses succeed in teaching this lesson, even a day or two prior to an

operation. It is not requisite to confine the patient to bed after the operation; but in some instances individuals prefer to lie still for a few days, especially if they feel weak from the loss of blood. The state of the tongue, before or after the operation, must not be taken alone as indicative of the patient's condition. All persons afflicted with cleft palate are liable to a dry, rough, and often coated tongue—the result of the constant passage of air in respiration over the surface opposed to the fissure. The injury, from the operation, to the soft tissues of the roof generally sets up a slight degree of feverish excitement, with a very coated tongue for a few days. This condition of tongue must not be taken to indicate the want of purgative medicine. In an instance under the author's notice, this state of the tongue was mistaken by a junior for a symptom of some great general disturbance of system, and to remove it, two consecutive doses of calomel were administered within four days: the patient became salivated, and the wound, which had been most satisfactorily united, gave way entirely a week after the operation.

A practical hint may here be useful with respect to use of sponges during any operation for the closure of cleft palate. Many small sponges fastened to short sticks, or fixed in short forceps, should be provided to mop out blood and saliva from the mouth. It will save time and trouble if these sponges are squeezed in a dry towel by the attendant nurse, as soon as each has been used by the surgeon or his assistant. It is then at once ready for use again; but if washed first in water and then dried on the towel much unnecessary time is lost, and no better result effected.

It may be asked what amount of improvement in articulation and speech is effected by the operation, in patients who successfully undergo it. Dr. Warren states: 'There is generally more facility of speech, which, so far as it has been in my power to watch patients at a distance, is constantly improving. A young man was present at a meeting of the Boston Society for Medical Improvement, about two years after the operation, and it was difficult to discover the least imperfection in his speech, although it had previously excluded him from society.'¹

The author has found that in many cases the improvement has been most marked and satisfactory; and, in almost all, sufficient to render what was formerly unintelligible now readily comprehended: in one case, a stranger could not have detected a defect in articulation, on the delivery of a long sentence, three years after the closure of the entire palate. In all cases time is requisite, and much pains must be taken by the individual to acquire the power to articulate clearly such letters and words as, without a roof to the mouth, the tongue cannot command. It becomes, in fact, a task to the patient to learn how to pronounce correctly and distinctly a new dialect. The condition of the upper incisors is often very defective in cases of complete cleft, and when the cleft has extended through the alveolar ridge. Such cases should be placed in the hands of an experienced dentist, when the work of the surgeon is finished; for this irregularity of the teeth will often form a complete impediment to the improvement in articulation, although the palate may be most satisfactorily closed. The substitution of artificial teeth in front, in place of the defective ones often seen in these cases, is not only of considerable assistance towards improving the power to articulate more distinctly, but also materially lessens what may become a very conspicuous deformity.

It would be invidious to the task the author has undertaken, in writing this article, as well as deficient in respect to those who have devoted attention to the subject it refers to, were he, in conclusion, not to mention the names of Roux, Cloquet, Mettauer, Mütter, Pancoast, and Dieffenbach, with those of Warren, Avery Fergusson, Anlandale, and Thomas Smith. Each has so far aided in turn to improve this once apparently difficult and almost hopeless operation, that it can now be confidently looked upon as certain to effect closure of the most extensive cleft, and almost certain to improve thereby the most defective articulation.

¹ *Amer. Journ. of Med. Sc.*, April 1848.

DISEASES OF THE LIPS.

The congenital defects of the lips and mouth, and the treatment applicable to each, are described elsewhere in this work ; as also the diseases of the tongue, and their treatment. In the following section will be described the diseases of the lips, jaws, and floor of the mouth.

The diseases of the lips are usually so marked, that they greatly affect the appearance of the individual ; and they are often so serious, that they demand the most careful attention of the surgeon.

Simple '*cracked lip*,' when superficial, may be the result of long-continued cold weather, acting upon a constitution somewhat out of order. The crack is usually near to or at the middle of the lip ; is not deeper than through the mucous covering ; is often excessively painful when stretched, and readily bleeds if its edges be accidentally and suddenly separated. It may generally be relieved by slight attention to constitutional measures ; an alterative, with aperients, if requisite, or such other remedies as the condition of the patient may indicate. The application of caustic will often relieve the pain at once ; and some simple salve constantly applied keeps the surface soft and supple, and prevents its edges from getting dry and tender.

Should such a slight but painful crack be neglected in early life, and no measures taken to relieve the patient of this troublesome recurring sore, it will often happen that the crack deepens, and becomes more permanent in character : it becomes located in the part ; and appears sometimes so deep, that it might be supposed that the middle line of the lip had been grooved out by ulceration ; a very unsightly furrow, occasionally of considerable depth, is thus formed, to the great deterioration of the personal appearance of the individual. Under such circumstances, the relief, which in former years would have been readily obtained, is now no longer so available, for though the ulcerated base of the furrow may heal under judicious treatment, it will leave a chink or gap in the middle of the lip ; and nothing short of paring its edges will remedy it. Under these circumstances, an operation may be recommended and undertaken, should the patient be in any degree desirous to have the disfigurement removed. The edges when pared should be brought together with one or two fine sutures.

Slight superficial fissures, indicated by their white lines, are occasionally to be observed on the upper and lower lips, in children as well as in adults : presenting in appearance as if at some former period slight ulceration had existed, though now healed and sound. If the teeth in the child be examined, they will be usually found to mark the characteristics of congenital syphilis ; and occasionally other symptoms of hereditary taint will present themselves, or may be detected as having existed. These marked fissures of the lips have been constantly observed to be associated with an inherited stain.

Cracks of a severe character are generally observed in the under lip ; but fissures are not at all uncommon in the upper one. These usually occur in children, and are mostly associated with, if not always indicative of, a scrofulous constitution ; enlarged cervical lymphatic glands are constantly present in such children. Such a condition of lip is often obstinately persistent, and can only be combated by such measures as are advisable for the improvement of the general health. If very painful, an occasional application of a strong solution of nitrate of silver will relieve the extreme sensibility, for this will be sometimes very distressing in the movements of the lips ; indeed so much so occasionally, that it interferes with the ready and comfortable use of the lip in conversation or during eating.

Fissures or ulcers of the commissures of the lips, or of their inner surfaces, should be very carefully looked to. In children they are usually transient, innocent, and associated with some passing constitutional disturbance ; or more obstinate, and grafted on a strumous habit. In adults, or after the period of childhood, such ulcerations or cracks about the commissures must be regarded with extreme care and some suspicion, under apparently the most innocent and unsuspecting circumstances :

as a rule, they are the results of former syphilitic taint, and form one of the numerous varieties of secondary syphilitic affections; other indications, confirmatory of such contamination, will seldom be found wanting; and the condition of the part will be subservient to the treatment adopted for the general condition of the patient.

A troublesome, and often a recurring evil, which the practitioner has to combat, is the tendency, in some persons, of inflammation of the mucous membrane of the mouth to run into aphthous ulcers. Such ulcers sometimes become deep, and take some days before they assume any tendency to heal. They occur on the side of the tongue, the lips, and frequently on the frænum of the tongue. They are always painful, sometimes exquisitely so; and their extreme tenderness may last many days, though the ulcer itself be not more than the flat surface of a split pea. The ulcer is generally ashy on its surface, as if covered with a superficial slough of mucous membrane; the surrounding membrane is red, and slightly swollen.

These ulcers, whether aphthous or more extensive, are generally attendant on some constitutional disturbance. In some individuals they constantly recur; and in such persons, either some peculiar defect in health, or, perhaps, some local climatic or other influences, may be their exciting cause. The pain of the ulcer can be at once relieved by touching the surface gently with a point of nitrate of silver. It is as satisfactory as it is unaccountable, to observe how immediately the application of this caustic removes the often exquisite pain—pain which may render the patient almost unable to eat or talk. The ulcer usually ceases to be felt after the caustic is once applied, and heals without further trouble; a second application is rarely requisite.

The constitutional measures must be guided by the circumstances of the case, as the recurring form of ulcer is usually associated with a delicate state of health. Every attention must be given to the improvement and invigoration of the system. But medicine will frequently fail to produce that which change of air, soil, scene, and circumstances effect in a short time, and as frequently in an unexpected manner.

A very painful, not unfrequently a very troublesome, and sometimes a serious character of ulceration is observed to attack the mucous membrane of the mouth in children—especially those of the lower classes. It may occur in several smaller patches in different parts of the mouth, or in a larger single patch implicating a great portion of the inner surface of the cheek. Usually, at first it appears wholly confined to the mucous surface; occasionally, if not checked, it will run deeper, and implicate and destroy a considerable surface of the mucous and subjacent tissues. It commences in the mucous membrane, first, as if a slough had attacked it; then superficial ulceration follows, and this may extend in surface, as well as in depth; and if not arrested, may destroy so much of the soft tissues, that when reparation and healing are established, the resulting cicatrix will form an effective bar to the free movements of the lower jaw, and thus occasion more or less difficulty in the introduction of solid food into the mouth.

This condition of ulcer is always one of excessive pain: all movements of tongue or mouth, or contact of food, greatly aggravate it; and these circumstances, added to the febrile disturbance, or constitutional state of the patient, interfere materially with the child taking an amount of nourishment necessary to combat the evil effects of the malady.

As regards treatment, the administration of various tonics is usually recommended, and locally the application of numerous washes—chlorate of potash given internally, or used as a gargle, is highly commended. But after watching such treatment in many cases, too often with very unsatisfactory results, the author had recourse to the use of opium with very marked, and even rapid relief. In children, the use of opium must necessarily be very guarded, and it should only be given in very small doses. It is best to commence with one or two drops of laudanum every four or five hours, according to its effect. The dose should be repeated as required, provided the child be not drowsy, but withheld until drowsiness has disappeared.

The opiate appears to act beneficially, by first relieving the pain the child suffers in the attempt to take food, and this relief is most marked soon after the administration of the medicine. Whether it is this alone, or whether opium here, as in other conditions of ulceration and sloughing, acts specifically, we do not undertake to explain. If it alone enables the child to take nourishment, it carries with its administration a great boon. The child, relieved of pain, commences to take food without discomfort, and soon begins to improve in condition: the swelling about the mouth subsides, the sores put on a healthy action, and cicatrisation follows in a most satisfactory manner. In two cases, lately under the writer's care, no other drug was had recourse to during the stage of ulceration; food was the only tonic given, and local applications had no place in the treatment. The relief at once was most marked, improvement rapid, and convalescence most satisfactory.

Cancrum oris is treated of in the essay on 'Gangrene,' vol. i., p. 142.

It is apt to occur in children of the ill-fed and poorer classes; not unfrequently the attendant of a severe attack of scarlet or other low form of fever.

Sir Joseph Fayrer informs the author that this same condition of sloughing of the lips and cheeks is observed frequently in adults in India, the subject of splenic enlargement, and is frequently seen to produce frightful disfigurement and contraction of the mouth, when the patient recovers from the immediate sloughing. In this country the disease appears to be confined to childhood.

Vascular growths of the lips, &c.—The tissues of the lips and cheeks are favourite localities for the commencement of nævi, or vascular growths, whether of arterial or venous constituents. Such masses are unsightly at best, and are usually brought to the notice of the surgeon at an early period for treatment. The nature of the treatment is necessarily various, and the variety in treatment is dependent in a measure on the amount of the diseased structure. The nævus may be but a small red superficial patchwork of vessels; or it may be a large soft spongy cluster of veins, spreading over a very large section of one side of the face. The small arterial bright vascular patches are most common; though often a very large spongy venous nævus on the cheek may be observed in very early life.

When a small arterial nævus occurs on the margin of the inner surface of either lip, and is entirely superficial, it may be disposed of in several ways; but the application of the ligature is the most rapid, the most certain, and not more painful than any other. A needle passed through the base, and a fine ligature tied under the needle tightly round the mass, rapidly and surely effects its removal. In the course of a few days, the slough will have separated; and in a few more, the wound, which at first may appear formidable after the removal of the slough, quickly contracts and cicatrises.

If the diseased mass of vessels is larger, and dips into the substance of the lip, and has not spread laterally, but involves more in depth than in breadth, it may become a question whether it would be better to cut it out, as in an operation for cancer of the lip, or to destroy it by repeated introduction of ligatures through its substance, to be tied tightly, so that the mass be cut up into several pieces. If the mass involves the whole thickness of the lip and the corresponding surfaces of mucous membrane and skin, and, though extending towards the root of the lip, does not spread laterally, and can therefore be readily removed by incision, there are reasons for such treatment being preferred. The disease is at once got rid of; the relief is effectual; the operation is simple; the recovery is quick; and the scar left after union is but slight. The only precaution requisite in the performance of such an operation is to take care that the incisions are made through healthy tissue, and beyond the diseased vessels. The margins of the wound are to be brought together, as in the operation for hare-lip.

But rather than sacrifice skin or mucous membrane, if either or both are much implicated, it is far preferable to have recourse to ligature; if the disease spreads laterally, or extends in any degree into the cheek, ligature alone must be used.

When ligatures are applied to such nævi of the lips and cheeks, it should always

be borne in mind that scar must be avoided as much as possible, and mucous membrane saved as much as can be. The one is an eye-sore; the loss of the other is apt to produce distortion of mouth and a contracted cavity. Therefore, in using a ligature for *nævus* of the face, it is best to pass the thread entirely subcutaneously, and to tie it at the common point, where it was made to enter and emerge from the skin, so that no portion of the latter be destroyed. One ligature may be sufficient in slight cases; but in others several may be requisite to completely obliterate and destroy the diseased structure. The object to be kept in view in introducing the ligatures, is to effect the entire division of the diseased mass of vessels in several directions—that, in fact, they be cut into several pieces; so that if, in the first instance, a ligature be introduced round a portion of the tumour, in the second operation, one should be passed across; that each ligature should act on a fresh part; that ultimately the original mass may be divided into so many portions as will insure the consolidation of all the diseased tissue.

If the ligature be introduced on a needle at one point, and carried partly round the mass subcutaneously, and brought out at some distant point—again introduced and carried in or through until it reach the original puncture, and the ligature then tightly tied at this opening—no skin need be destroyed or mucous membrane cut or damaged. Each ligature should be tied as tightly as possible. It will soon cut its way free. The ends of the ligature should not be left too short; otherwise they may become buried in the wound in the subsequent swelling of the parts, and probably would cause suppuration to a greater extent than desirable, or even occasion some difficulty or delay, from being retained in the wound. The more tight the ligature is tied, the more speedy will be its release from the tissues which it grasps.

Vaccination should only be tried in very small *nævi*; the introduction of caustics, setons, the injection of perchloride of iron, each have their advocates; but none of these secure more effectual obliteration of the *nævus* than the ligature: they often fail to do so as rapidly; they often set up more irritation than is requisite for the purpose in view; they sometimes cause the skin to slough; and they are more painful in adoption, inasmuch as, being slower in action, their application must generally be often repeated before a satisfactory result is insured. The galvanic cautery has often been employed by the author; but after a great number of experiments in the treatment of such cases, he is satisfied that subcutaneous ligature will invariably be found quickest in action, most effectual in result, less disfiguring as regards scar, and, so far, less painful than any other kind of treatment. This is the case whether a *nævus* of the lip be large or small; unless the case be more suitable for the knife.

These remarks apply to the general treatment of arterial *nævi*, but when the *nævoid* tissue is evidently of venous character, and not too large, it will be found best to dissect them out. A clean incision through the skin sufficiently long to allow of this dissection is followed by little disfigurement. If in the eyelid, the cicatrix is often lost in the folds of the skin; or if in the lips, the mass can generally be attacked from within by cutting through the mucous surface alone. The author has frequently removed such *nævi* from the forehead, nose, eyelids, and lips, leaving in the course of a year or two hardly a perceptible scar. In dissecting out such small *nævi* the only precaution is to avoid cutting into the *nævoid* tissue itself, but dissecting beyond or outside of it. There is generally but very slight bleeding, as healthy vessels are alone cut through, but should the *nævoid* structure be accidentally wounded, more free bleeding will occur, as diseased vessels do not contract in the manner healthy ones do when divided. If, however, troublesome bleeding does take place, the bleeding point, or mass, may be readily taken up by forceps, and a ligature passed through or around it, and the dissection proceeded with. We have never found much bleeding follow such an operation: more frequently the remark applies that less bleeding takes place than may be anticipated. It must not be forgotten that venous *nævi* occasionally become arrested in growth, or degenerate, and even disappear without an surgical interference.

Cancer of the lip may be said to be confined to the lower lip; so rare is it in the upper; it certainly occurs more frequently in the male than in the female, the proportion being relatively large in the stronger sex.

The characteristics of cancer affecting the lip deserve particular attention. As a rule, we may say it is found to consist of the epithelial variety.

'Epithelial cancer has its primary seat, with very rare exceptions, in, or just beneath, some portion of skin or mucous membrane. Its most frequent locality is the lower lip, at or near the junction of the skin and mucous membrane.'¹ Commencing sometimes as a small warty growth on the lip; sometimes as if the mucous membrane were excoriated, with the excoriation resting on an inflamed and thickened base; sometimes as a small, indolent tubercle: the condition which does not at first excite suspicion, by degrees is seen to alter and the growth to increase. The wart grows in breadth and thickness; the excoriation becomes deeper, and rougher on its surface; the tubercle peels and ulcerates, scabs and peels again; until, sooner or later, the persistence of the mass, or the heat and pain of the part, attracts the more serious attention of the patient, and he then seeks for relief.

It is unnecessary here to enter upon the question of the pathology of cancer, or of its cachexia; the subject is discussed in the essay on Tumours, Vol. I.

The diagnosis of cancer of the lip may at first sight appear simple enough; and yet a certain degree of caution must be observed, ere an opinion be definitely arrived at, as to the precise character of a hardened sore, or of a raised tubercle of the lower lip. It has occurred to the author, and no doubt to many others, to point out, that a previously supposed cancer of the lip was but a chancre: a chancre of the lip has been mistaken for the more serious malignant sore. The surface under both conditions may be superficially excoriated; the lip may be thickened at the part; the sore may rest on a hardened base; and there may be the additional suspicious circumstance of attendant enlarged glands in the submaxillary region. It must, however, be borne in mind, that cancer of the lip is somewhat slow in its progress: that the cervical glands do not usually indicate the more grave implication of the constitution at an early period: whereas in chancre the glandular enlargement would be apparent in six or eight weeks, at the latest, from the first appearance of the sore; and probably, if no specific treatment have been adopted, other evidences of secondary symptoms, such as eruption, sore throat, &c, would be manifest within six weeks of the first infection. As a mistake in diagnosis between cancer and chancre of the lip may occasionally occur, a few remarks in passing, on that subject, will probably not be useless.

Cancer of the lip is a disease of advancing, if not of advanced life; but man is often deprived, and experience teaches us that age need not be taken as a bar to the occurrence of a chancre of the lip.

A gentleman, past the meridian of life, applied to the author with a condition of lip which had excited suspicions as to its cancerous character. The appearance of the sore itself was extremely deceptive: scattered and isolated glands, slightly enlarged, and hard, were to be felt in the submaxillary regions; and his position and circumstances in life rendered it most improbable that a chancre could have been contracted on such a part. This sore was found to be accompanied by a commencing faint lichenous eruption. The patient was put under a mild course of mercury, and rapidly recovered; the hardness at the base of the sore entirely disappeared.

The characteristics of the two affections may thus be summed up: chancre of the lip may occur at any period of life, and is as often seen on the upper as the lower lip. Youth is the most probable period of the infection; and, it may be said, is most frequently observed in women: it sooner or later forms a superficial sore, raised on a base of an almost cartilaginous consistence: the surface appears more like an excoriation than an ulcer; or the surface may have cicatrised and the hard base remain. The glands of the submaxillary spaces enlarge at an early period, some six or eight weeks after the sore commences; and though hard, small, and scattered usually, they sometimes attain a large size. In one instance which came under the

¹ Paget's *Surgical Pathology*, vol. ii p. 419.

author's notice, the glands on the right side were very much enlarged, and on the inside of the right half of the lower lip was a large hard cicatrix, the original sore of which had entirely healed some weeks previously. Secondary symptoms will sooner or later appear, unless early treatment be adopted.

Cancer of the lip is generally a disease of advanced life, and usually affects the lower lip; is most frequent in men; its progress is not uniform, nor often rapid; it does not implicate the absorbent glands at so early a period as chancre; does never thoroughly heal up and cicatrise or lose its hard base like chancre. The disease is usually of the epithelial variety of cancer, and varies a good deal in its method of commencement, in its progress, its growth, and its appearance; while the characteristics of chancre are uniform in most persons. Cancer always contaminates the absorbents, if allowed to run its course unchecked; ultimately it destroys, locally, all tissues in contact with its surface; the whole lip may be affected; and large cancerous masses may exist, at the same time, from the symphysis to the clavicle; and death ultimately follows.

The treatment of cancer of the lip usually resolves itself into removal by knife, or destruction by caustic. In the opinion of the author, it should be entirely restricted to that of the knife; and the earlier such treatment is adopted, the better the prospect of prolonging life.

The surgeon having decided to remove a cancer of the lip with the knife, the patient should be seated in front with his head steadily supported by an assistant; or placed in the recumbent position if an anæsthetic be used. If the disease occupy but a small portion of the lip, the mass may be removed entirely by a V-shaped cut through the healthy structure. The lip may be transfixed with a thin straight knife, and then cut upwards on either side of the diseased tissue: an assistant should hold the flaps as they are liberated from the diseased part. The flaps are to be brought together with pins and the twisted suture, or by sutures alone; care being taken that the meeting line of mucous membrane and skin be accurately adjusted. One, two, or three pins may be requisite; some surgeons prefer sutures without pins; and silver sutures answer the purpose very satisfactorily. If pins be used, as soon as they are fixed by suture, the sharp-pointed ends should be cut off, and the remaining ends so protected that they be not readily caught by the dress, &c. of persons in attendance, otherwise the patient runs the risk of being accidentally much hurt, for want of a little foresight. In all these operations the pins or sutures should be removed at the end of forty-eight hours at the latest, and the wound supported by adhesive plaster.

If a large surface of the lip be affected, and the disease be superficial, it may be readily removed by a semicircular sweep of the knife, or a cut with a pair of curved scissors; in either case the opposed edges of skin and mucous membrane should be brought together with sutures. In the incisions through the lip, the labial arteries bleed freely. With the aid of the pins and twisted suture the hæmorrhage is readily and effectually checked; with the semicircular incision a ligature or two may be requisite.

It will save some little inconvenience, and also pain, to have the sutures well oiled before they are twisted round the protruding extremities of the pins: by using this precaution, it will be easy to remove the sutures subsequently; when not oiled, they adhere to the pins and to the skin, and always occasion pain on removal.

The use of caustics, in cases of epithelial or other cancers of the lip, is but waste of time, and an unnecessary infliction of suffering; provided the disease be not too far advanced for removal by the scalpel. The knife should always be used when practicable; caustic, only when the disease is too far advanced for removal by the knife. But even then it is doubtful whether any application of caustic, by retarding growth or destroying material, compensates for the pain, and often exquisite suffering, which is inflicted by its use. If caustic be decided on, the most efficient is the actual cautery used in the form of the benzoline cautery, or the chloride of zinc applied in the form of a paste.

The advantages of operating early can only be appreciated when compared with the

more rapid results of a case which is allowed to run its course unmolested. But under the most favourable circumstances, we can only expect the operation of removal to relieve for a time; the disease usually returns, and generally shows itself in the glands of the submaxillary region. These in time increase to a great size; the skin over them ulcerates and sloughs; an ulcerated and fungoid surface discharges profusely, and often bleeds largely; and life is thus drained away. We cannot here more fully discuss the advantages of the removal of cancerous affections of the lip; but as such affections are not ultimately amenable to any treatment, nor the disease ever eradicated by topical remedies, their entire removal offers the speediest prospect of present relief; and though such a measure should be adopted as soon as the disease is decided to be cancer, the remedy is at best but a choice of evils, and must not be held out as one of radical benefit.

Cases are, however, occasionally met with in which somewhat more satisfactory results follow removal. A gentleman had suffered for some few years from a troublesome superficial ulceration on the right side of the upper lip, and part of the right cheek above the affected portion of the lip. This had been kept in check, and had occasionally healed under the application of arsenical and other caustic preparations; attended, however, by much suffering whenever under such treatment. Though each application of caustic was followed by healing, each cicatrization was succeeded by fresh ulceration. This condition continued till the right half of the upper lip became thickened to some extent, the ulceration was observed to be less amenable to treatment, and much constant burning pain was established in the part. The author was now consulted. The ulceration, although somewhat superficial, was supported on a thickened and hardened base. It implicated a patch of the right cheek, the size of half-a-crown piece, and slightly encroached on the adjacent ala of the nose at its lower border. The right half of the upper lip was much thickened, and in its substance could be felt some suspicious hard spots, or tubercles, which conveyed the impression to the touch of incipient epithelioma. The whole of the diseased mass was removed by the knife. One incision was carried from near the inner angle of the eyelids downwards, so as to include the ulcerated portion of the ala nasi, and then through the centre of the upper lip to its free border. A second incision was commenced at the point of the first above, and carried down to the angle of the mouth. The piece between these incisions was then dissected freely from its attachments. The divided lip was brought together by means of hair-lip pins and twisted threads, and the upper portion of the wound by silver wire sutures. The mouth was at first very much drawn to one side, and the nose also, but to a less extent. The entire wound healed quickly and most satisfactorily.

The examination of the diseased portion proved it to be true epithelioma. It is five years since the operation, and when seen this year (1882) the patient remained perfectly well; and there was but little disfigurement of the face.

Cysts of the lip are not infrequent. They are generally observed near the free border, or inner surface; usually of the lower lip. They sometimes increase to an inconvenient size. On the margin of the lip they seldom project beyond the mucous membrane; the skin is usually free. They are generally well raised from the surface; covered by very thin membrane; usually semi-transparent, but occasionally somewhat discoloured and of a venous hue, as if veins traversed or opened into a cavity.¹ They contain either viscid clear mucus, much like the contents of the cysts termed *ranulae*; or sometimes a darkish fluid of thick consistence. They are generally single, though their surface and shape may be irregular. They seldom grow large; though this may be the result of locality, as the surgeon is usually required to remedy the evil before it occasions much inconvenience, or becomes unsightly.

Such cysts are usually innocent in their character; do not recur in the part when effectually treated; nor are they congenital, unless of that variety alluded to as

¹ 'Cysts formed of dilated portions of blood-vessels shut off from the main stream.'—Paget, *op. cit.* vol. ii. p. 27.

connected with blood-vessels. These cysts are often not larger than small peas, or from that to the size of a small walnut; painless; indifferent to being handled; and only inconvenient from size or disfigurement. They occasionally remain stationary for life; are then usually small in size, and frequently discoloured; the more transparent ones have the greatest tendency to increase, as if dependent on the secretion of a gland, which probably, having had its duct obstructed, has given rise to the formation of the cyst.

The treatment to be adopted in such cases is very simple and usually satisfactory. The cyst should be freely divided, and, when entirely emptied, it is best to wipe the interior with dry lint, then freely apply strong nitric acid to the whole surface of the lining membrane. Though the treatment be rather sharp for the moment, the pain soon subsides, and the patient will be able to eat and talk as usual. No surgeon should be satisfied with simply puncturing such cysts; a puncture, or even a small incision, will frequently close before the cyst is obliterated; and in a few days it becomes as large as it was originally. Even after the application of nitric acid, unless the opening be free, and care taken to keep it so, until the cyst be entirely destroyed, the accumulation of fluid is very apt to recur. It is a good precaution to touch the edges of the opening with nitric acid for a few days consecutively, to insure its not closing until suppuration be fully established, so that the lining membrane be obliterated. Occasionally a cyst in the lip is complicated with some solid growth. Such growths are usually somewhat of a glandular nature,¹ and very favourable for removal. These tumours are not common. They resemble, to some extent, the mammary glandular tumours in consistence and character; or 'they may appear intermediate between the foregoing and those tumours which are found over, or near, the parotid gland, and consist of mixed glandular and cartilaginous tissue.'²

Sir J. Paget refers to a case removed by himself from the upper lip of a man, and describes a second case, which occurred under Mr. Lloyd's care, in a man who had a tumour in his upper lip for twelve years, when it was removed. 'The tumour was firm, slightly lobed, yellowish-white, smooth. In general aspect it resembled the mixed tumours over the parotid; but its minute structure presented as perfect an imitation of lobulated or acinous gland-structure as any mammary gland.'³

The lips, more especially the upper one, will occasionally be abnormally prominent, thickened, and even somewhat everted in strumous children, or in children in whom symptoms of inherited syphilis are well marked. In the former condition, there is not much benefit to be derived from any specific treatment; but should the child grow up under favourable sanitary and other general domestic conditions, this disfigurement will probably materially diminish, even should it not entirely disappear. But thickened lips, due to syphilitic taint, are occasionally met with in adults, as well as in children. The author has had lately under his care a patient in whom both upper and lower lips became considerably hypertrophied. They were prominent, somewhat everted, slightly marked with superficial furrows, and conveyed the impression to the eye that the enlargement must be due to dropsical effusion. There was no corresponding oedema of the cheeks, nor any enlarged glands to be discovered in the submaxillary spaces. The patient complained that they felt hot and painful. He had long been the subject of syphilis—patches of white mucous membrane were well marked on the inside of cheeks and lips. His condition greatly improved under treatment, especially as regards the lower lip, which returned almost to its natural size. Another form of thickened lip will be found due to hypertrophy of submucous gland cells. 'On removing the hypertrophied mucous membrane, a number of small granular bodies, the size of hemp seeds, and made up of gland-cells, are always found underlying a healthy mucous membrane.'⁴ This enlargement shows itself by a prominence or bulging rather of the mucous membrane on each side of the median line, rather like a fulness of the inner surfaces

¹ For a specimen, see Museum of St. George's Hospital; referred to also by Paget, *Surgical Pathology*, vol. ii. p. 73.

² Paget, vol. ii. p. 262.

³ *Ibid.* p. 263.

⁴ Bryant, *Practice of Surgery*, vol. i. p. 515.

of this portion of the lip than actual general thickening. This is dependent on the increase of size of the glands existing in these parts. Mr. Bryant states that when removed, by careful excision of the diseased submucous tissue, it does not recur.

Cysts of the mouth may be congenital, or the result of obstructed ducts, *ranulæ*, or possibly bursæ between the muscles of the tongue.

Congenital cysts of the mouth are not frequent, though they occur sufficiently often to be familiar enough to surgeons. Mr. Caesar Hawkins long ago drew attention to their real character.¹ Usually such cysts are single, and may increase to a large size; or they may be multilocular and numerous, and occupy a considerable portion of the floor of the mouth. Whether single or compound, they will usually be found between the lower jaw and the tongue; if large, pressing the floor of the mouth forwards and upwards, and the submaxillary soft tissues outwards and downwards.

An infant three weeks old was sent to the author by Mr. Frank Buckland, then assistant-surgeon of the Second Life-Guards. The mother found that the child suckled with increasing difficulty during the last few days, in consequence of a swelling on both sides of the floor of the mouth, which was pushing up the tongue, and had much widened the lower jaw. It had also encroached backwards so as to press somewhat on the larynx and pharynx; respiration was somewhat impeded; deglutition was slow and difficult. Under the tongue and on both sides of the mouth there projected a lobulated irregular cystic mass; some portions of which, especially on the left side, were so prominent, that the tongue was pushed upwards by it, and the tumour bulged out between the tongue and the lower jaw, to such an extent, that the infant could not close its lips. An irregular lobulated swelling projected on each side of the throat, immediately below the lower jaw.

The cysts projecting between the tongue and lower jaw were thin and pellucid, the membrane covering them pale-coloured, and free of vessels on its surface.

A seton passed through a cyst on the left side soon allowed it to collapse; a thin purely transparent fluid oozed out through the punctures. On other days other threads were passed through some of the more prominent cysts, while some were punctured. The partial reduction of the sublingual swelling enabled the infant to partake more freely of food, and for some days a slight improvement was observed in his condition. This was but transient; evidently other and deeper cysts became larger; gradual increase of dysphagia and dyspnoea supervened; and the infant died, greatly emaciated, the sixth week after its first visit to the hospital.

On examination, it was found that this cystic formation involved all the tissues between the mucous membrane of the floor of the mouth and the skin covering the submaxillary region; so that not only did the mass of cysts (it might be termed a multilocular cystic tumour) project upwards in the mouth, but downwards on both sides, in the submaxillary spaces. On a section of the tongue, the whole muscular structure was seen studded with cysts; small and millet-like in some parts, rather larger in others; some single, others multilocular. The larger ones were generally multilocular, with bands running across and around their walls.²

Other forms or characters of cysts are occasionally observed in the mouth, sometimes between the gum and the cheek.

Sir J. Paget describes a case of this nature, which occurred in a woman, in whom a soft elastic swelling pushed out the thin mucous membrane of the upper jaw, producing externally an appearance somewhat similar, at first sight, to distension of the antrum. An incision into the cyst allowed the escape of nearly an ounce of turbid brownish fluid, containing crystals of cholesterine.

Cysts connected with defective development of teeth, 'dentigerous cysts,' usually confined to the alveolar regions of the maxillæ, are not uncommon. Their history and treatment are related by Mr. Salter, and will be found in the preceding essay.

Obstructions of mucous follicles occasionally give rise to the formation of mucous cysts, already spoken of; the obstruction of the submaxillary or sublingual ducts may be productive of the cysts termed '*ranulæ*.'

A more rare, but well-known character of cyst is met with amongst the soft tissues of the submaxillary region, usually between the symphysis and angle of the lower jaw, and more or less deeply seated between the floor of the mouth and the inner surface of the bone. This cyst will be found to contain sebaceous matter, mixed not

¹ *Med.-Chir. Trans.* vol. xxii. p. 231.

² The preparation is in St. George's Hospital Museum.

unfrequently with hair or other evidences of its dermoid origin. The amount of its contents is sometimes considerable, due probably to the age of the cyst; for its very gradual distension has allowed it to attain a size larger than would otherwise be expected, and this without producing local inconvenience or trouble during the greater period of its existence. The contents are consequently often offensive, and semi-purulent when evacuated; the larger proportion will be, however, the result of epithelial accumulation.

Its existence may have been noticed from birth; but as far as experience enables us to arrive at a conclusion on this point, it appears more frequently to become evident at some later period of life; for, although in all likelihood congenital, it may originate in so small a cavity, and may so slowly fill, that it will only make itself conspicuous to sight or be detected by touch at some subsequent period.

The opinion arrived at that such cases are usually congenital, that their origin is due to imperfect closure of a branchial fissure, and that they are closely allied to such cysts of a dermoid character as are frequently met with in children, in the cheek or at the orbital edges, appears to be founded on very carefully sifted evidence. Many writers have drawn attention to this subject, but Mons. Jean Cusset¹ has more recently and in a very complete manner, in a memoir to which the reader is referred, described the abnormal conditions dependent on imperfect occlusion of branchial fissures, and the occasional consequent formation of such cysts.

The author was consulted by a gentleman with a large cyst below the angle of the jaw, and protruding forwards towards the median line: it projected much into the left side of the floor of the mouth, and the tongue was consequently pushed somewhat to the opposite side. Articulation was slightly interfered with, and some difficulty was experienced in mastication and deglutition. Some fifteen years previously this patient had been operated on by Sir W. Fergusson for what was described as a somewhat similar swelling. An attempt was made to dissect it out. A large portion of the cyst had evidently been removed, but most probably a small portion had been left behind. There was considerable bleeding at the time of the operation. About three years subsequently a swelling recommenced in the original seat of the tumour, and had gradually increased till seen by the author. The cyst was freely laid open from without, and about a pint of semi-fluid sebaceous matter was observed to escape, the forefinger introduced into the cyst detected a cavity, which, besides extending along a considerable portion of the floor of the mouth, ran backwards and upwards inside the ramus of the jaw, and apparently terminated just behind the tonsil and in close proximity to the pharynx, from which it was separated by a very thin septum. The cyst was freely washed out daily with a lotion (of 1 in 20) of carbolic acid until it had contracted and become perfectly closed. During the process of washing out, and especially at the earlier period of treatment, large and numerous flakes of epithelium would be daily removed, and this desquamation continued almost to the latest date. It is now four years since the last operation, and the patient has remained free from recurrence of any swelling.

A young woman was admitted into St. George's Hospital, with a considerable swelling on the right side of her mouth and neck. The swelling bulged into the mouth; had displaced the tongue to the opposite side; and protruded downwards in the submaxillary region. The swelling was painless, but inconvenient from its size; it had been many years forming, and it was doubtful whether it was not congenital. A free incision through the portion projecting into the mouth allowed the escape of a large quantity of a thickish yellow fluid, most offensive and putrid in smell, similar to the contents of a suppurating sebaceous cyst. By degrees the cavity contracted and closed.

This patient returned to the hospital about three years afterwards. The cyst had again filled, and projected a good deal below the lower jaw. It was now opened by the author, in the neck, below the lower maxillary bone, and a large quantity of offensive sebaceous-looking fluid was evacuated; a seton was then passed through the cyst, and retained several days, until the cavity had become perfectly contracted. The opening soon closed, and, as far as could be ascertained, the cyst appeared to have been obliterated. Nothing more has been heard of the patient.

The deep seated connections of these latter cysts render their removal by knife,

if not nearly impossible, at any rate so hazardous, that any attempt to dissect them out had better be avoided, if free incision and daily washing out with some stimulating disinfectant offers a prospect, by destruction of their lining membrane, of their perfect contraction and so far eradication. A case, related by Fergusson, well illustrates the difficulties a surgeon may have to encounter in the attempt to remove the cyst by knife, to say nothing of the danger the patient may be placed in.¹

The diagnosis of cysts of the mouth is not often complicated: usually, fluctuation is very evident; as, frequently, the surface of a portion of the cyst projects into and on one side of the mouth, so that it may be seen covered only by mucous membrane; the walls are thin and pellucid; the contents visibly transparent, or slightly tinged from some accidental circumstance or individual peculiarity.

In other cases these cysts present more obscure conditions: they may lie deep among the muscles of the floor; or may press backwards and interfere with the movements of the larynx or pharynx; or a sanguineous tumour may be mistaken for a cyst, though sanguineous tumours are exceedingly rare in these parts.

Such serous and mucous cysts as we have referred to may be treated without hesitation, and without much danger. If very large, it may be as well to draw off a portion of the fluid, in the first instance; and subsequently have recourse to setons, or injections of iodine. But as in any operation in the region of the mouth and neck œdema may occur about the root of the tongue and the fauces, and interfere with deglutition or respiration, it is better to select the less irritating and most simple treatment, before proceeding to the more heroic.

In the treatment of *mucous* cysts of the mouth, a seton, or injection of iodine, will often be found inefficient; the cyst may fill again in a short time. If a portion of the cyst be cut away, the contents allowed to escape, and nitric acid applied freely to the interior, the treatment will generally be found successful. Some of the small, isolated, mucous cysts, situated immediately under the mucous membrane, may be readily removed by the knife; but the attempt to remove a large and more deeply-seated cyst is hazardous and unnecessary.

By laying the cyst freely open, in all probability it will close up from the bottom, or, at any rate, become so much diminished that ultimately a seton, or injection of iodine, will effect its obliteration. A silver wire may be used as a seton, if the cyst contents, by tapping, are proved to be clear and thin; but if opaque, dark-coloured, thick, or purulent, a free incision is the safest, the most effectual, and the least tedious treatment.

A large cyst opened by incision in the mouth, and found to contain purulent fluid, may not contract very rapidly, in consequence of matter bagging downwards in the neck, in the lower part of the sac. Under such circumstances, a small opening may be made under the jaw, and a drainage-tube introduced. But as a scar in the neck, especially in women, is always objectionable, such an opening had better be avoided unless absolutely requisite.

By far the greater number of the different varieties of cystic formations (independent of bone) will be found on the inner surface of the lips, the surface of the gums, or on the floor of the mouth; and the treatment above described may be followed accordingly, care being taken to ascertain first the character of the fluid contained; for should the contents be blood, the treatment should be different to that described.

Sanguineous cysts about the mouth are rare. When present, they are usually seen on the lips, near their free border. Instead of free incision, when deeper seated they should be treated with setons or ligatures, when superficial and accessible, they may be dissected out, or included in a ligature, like a *nevus*.

To sum up the evidence on the history of mucous or serous cystic affections of the mouth, we find that, in early life, they occur either singly or in clusters; are generally of a congenital nature; and are found most commonly on the floor of the mouth, or, in after life, on the surface of the gums. Venous or sanguineous cysts are generally observed in the lips and on their inner surface; are usually congenital,

¹ *Practical Surgery*, p. 509. 3rd edit.

and frequently stationary; in this they differ from other cysts. Sebaceous cysts, containing sometimes a mixture of epithelial, thick, white, and often putrid matter; hair growing from the lining membrane (which partakes of the character of cuticle); or loose hairs; bone or teeth—these have no peculiar affection for locality, are most capricious in their selection of spots for habitation, and may be found in any part of the mouth or its immediate neighbourhood. They are usually round, small, and, if immediately under the mucous membrane, appear like a white marble embedded in the areolar tissue. Their inclination is to grow slowly; so slowly, as already stated, that years may elapse before their presence occasions inconvenience. These may all be considered of the congenital variety. Mucous cysts, ranulae, cysts of the lips connected with portions of solid or glandular growth, some serous cysts, and those generally single, will be found to commence after birth, and at different ages. They usually occur before very advanced life.

☞ Solid growths of the lips and mouth, of a non-malignant, *i.e.* non-cancerous character, are not of many kinds, nor do they frequently occur. Labial glandular tumours have already been referred to. Occasionally a fatty tumour grows among the muscles of the tongue, or about the floor of the mouth. The diagnosis is usually simple, though when deep-seated it may puzzle the surgeon, until he cuts down the growth. Its tendency is generally to protrude towards the skin rather than towards the mouth; the constant movements of the tongue being usually sufficient to direct the mass towards the least resistant surface.

A fatty tumour need only be removed when of an inconvenient size. A free incision over its surface, below the jaw, will generally allow of its being readily dissected or dragged out.

The author removed one for a lady, forty years of age, who had been aware for some years of its existence, under the tongue and jaw, on the left side. On cutting freely down upon it, the lobes of fat were found to dip deeply into the floor of the mouth, round the mylo-hyoid muscle; but the whole was readily removed.

The chief danger attendant on such an operation is extension of inflammation and suppuration to the intermuscular tissue about the root of the neck. The lady alluded to had for some days considerable pain and difficulty in swallowing, but ultimately recovered.

Occasionally a calculus will be found impacted near the orifice of a salivary duct, which possibly may give rise to some obstruction and consequent distension. But this is not often the case; the calculus may not be able to escape, but the secretion of the gland usually finds its way past the calculus. We have seen the presence of a calculus in a salivary duct give rise to suppuration around it. Occasionally, from neglect or indifference, one has been known to acquire a size which would be usually considered an intolerable nuisance. Mr. Bryant mentions an instance in which a salivary calculus weighed 48 grains¹—and was a source of constant disturbance to the patient's comfort. It may be readily removed by a slight incision over it through the mucous membrane.

The condition, in infants, known as 'tongue-tie' is treated in the essay on DISEASES OF THE TONGUE.

The tumours which affect the maxillary bones will be found to consist of the (1) Cartilaginous; (2) Cystic; (3) Fibrous; (4) Myeloid; (5) Osseous; (6) Vascular; (7) Mucous, or Myxoma; (8) Cancerous.

It is not intended that the order in which they are placed should be taken as any indication of the relative frequency of these growths; it is simply intended to indicate all those which are found to attack these bones.

There are few points in practice which demand more careful consideration than the origin and outgrowth of these tumours. It is only by a most careful examination of each case that the surgeon can hope to arrive at a satisfactory diagnosis, or be enabled to decide with anything like confidence, whether recourse should be had to operative interference, or whether he should determine not to meddle unnecessarily

¹ Bryant, *Practice of Surgery*, vol. i. p. 518.

with a disease which offers no hope of benefit from treatment. In our observations with regard to the individual characteristics of these tumours we shall consider only their clinical aspect and general practical features; their more minute pathological characteristics and structure will be found fully described in the essay on TUMOURS, Vol. I.

Before entering into this examination, we think it desirable to refer to two other growths, not included in our list, but usually mentioned in most works on surgery in connection with diseases of the jaw. Either of these conditions might possibly be mistaken for some of those in our list, were not allusion made here to their occurrence as well as to their character. One is a growth from the gum; the other is an expansion of the alveolus, due to a diseased tooth-fang. Epulis is the name given to that from the gum. It will found fully described at p. 454. It is only here necessary to mention that the growth is generally owing to some irritation set up by a decayed tooth. It will be seen up from the gum, and often surrounding the tooth, is generally of a darkish or bright red colour, varies in size according to its duration, and often bleeds when examined. It not only grows from the gum, but often dips into, and is attached to, the lining membrane of the alveolus. The extraction of the offending tooth, and the removal of the growth by scoop, knife, or escharotic, is usually sufficient for its eradication. Should it, however, be found more intimately connected with periosteum or bone, or recur after removal, and subsequently prove troublesome, it will be probably found to partake of the myeloid character—a condition to be hereafter described.

Again, the base of the alveolar ridge may at any given point become so much expanded as to be mistaken for an osseous growth of the jaw. This expansion will be due simply to a peculiar diseased and enlarged condition of the tooth-fangs, known as an 'Odontome.'¹ It is relieved at once by the removal of the tooth, but is of sufficient importance to be mentioned here, although it may be said to fall more especially to the department of dental than to that of general surgery.

Cartilaginous tumours of the bones of the face are rare, and the upper and lower maxilla may be said to be almost free from their attacks.

Paget alludes to but one well-known case, which occurred in the upper jaw of a patient in Guy's Hospital. Mr. Beaumont, Professor of Surgery in the University of Toronto, has recorded an interesting case in the 'Royal Med. and Chir. Transactions,'² which occurred in a boy seven years of age, affected the lower jaw, and was successfully removed.

In the 'Museum of the College of Surgeons' is a wonderful specimen of one of these tumours, which implicates the greater portion of the lower jaw; it had been some eight years growing, and when the patient died, exhausted by its ravages, it measured two feet in circumference.

The symptoms and prognosis of enchondroma are the same, when it affects either of the jaw-bones, as in other parts of the body. These tumours of the jaws may be removed with much confidence of relief. The operation cannot be too early decided on; delay may be so far dangerous that a very rapid growth, by a short postponement, may really make the operation very severe and extremely hazardous.

In the removal of the smallest cartilaginous tumour, care should be taken that every particle of the surface of the bone from which it is growing be freely removed. In the removal of the larger tumours, it will depend on the involvement of the bone how much of it has to be removed. The greater portion of one side, or even the whole, of the lower jaw, or the whole of the upper maxillary bone, if involved, must necessarily be taken away. The disease will probably be restricted to one side in the upper jaw; in the lower it may more readily involve the greater part of the bone. The prognosis after operation is usually favourable; but it should not be overlooked that enchondroma sometimes recurs, and that in other cases the tumour grows rapidly, and large cysts are developed in its substance. Both these forms of enchondroma are apt to approach in character to that of cancerous tumours.

¹ For description, see p. 461.

² Vol. xxxiii. p. 243.

³ Museum Catalogue, No. 1034.

Cystic tumours of the jaw are not very uncommon.¹ We undertake their consideration in this place, in order to mark particularly the distinction which must always, pathologically, be made between the secondary cysts of bone resulting from degeneration of cartilaginous tumours, and the primary cystic tumours which attack the upper and lower maxillæ. The latter are seen to originate in the substance or from the surfaces of the jaw, under a variety of unexplained circumstances.

Cysts of the jaws are sometimes found to be connected with a diseased condition of a tooth-fang; or, more frequently, with a diseased action attendant on the development of the tooth-pulp—'dentigerous cysts.' (See p. 468.)

Specimens of simple primary cysts of the jaws, commencing in the substance of the bone, may be found in some of the museums of the metropolis. They expand the bone more or less, so as to take with them portions for their outer covering or walls, the remainder of which will be generally made up of a tough membranous substance. The contents are fluid, serous, or gelatinous, and of different shades of colour. 'This disease is usually of slow growth; and there have been instances in which the tumour of the jaw, formed by it, has acquired a large size.'²

FIG. 129. —Cystic Tumour of the Lower Jaw. (From the Museum of St. George's Hospital.

In the Museum of St. George's Hospital may be seen a preparation (fig. 129) which well illustrates the prominent features of a simple cystic tumour of the jaw. The tumour was removed from a woman forty-five years of age. It occupied on the right side the situation of the lower jaw, and extended from the second incisor to the condyle of the bone: it formed a large globular cyst, which occupied nearly the whole of the side of the face. It extended downwards over the upper portion of the neck; and inwards, displacing the tongue; it greatly interfered with speech and mastication. The principal part of the growth was upwards and outwards towards the malar bone, which was somewhat expanded and partly absorbed. In some parts the tumour appeared of bony hardness; in others very elastic. The integument covering it was not discoloured, and there was no enlargement of the neighbouring glands. The disease had been noticed about eighteen years before admission, when it formed a small hard incompressible lump, just over the angle of the jaw: it gave no pain; and for a long time its increase was extremely slow. About six months previous to her admission, it commenced to enlarge very rapidly. The cyst may be seen in the figure to extend from the symphysis to the right condyle.

See Stanley, *Diseases of the Bones*, p. 268; also, *DISEASES OF BONES*, Vol. I. p. 328.

² Stanley, *op. cit.* p. 267.

The parietes are partly osseous and partly membranous. The entire substance of the jaw-bone on this side has disappeared, and is replaced by the abnormal growth. When removed, the cyst appeared to be divided into several cells, which contained a transparent gelatinous fluid; though in the dried preparation there are but few indications of such divisions. The tumour was successfully removed; but the patient died subsequently from erysipelas.

In the Museum of the College of Surgeons there is a specimen of a cyst of the lower jaw, occupying the greater extent of the right side, and projecting outwards rather than upwards. It is oval in shape, and multilocular; the cells were filled with a glairy fluid. The diseased portion of the jaw was successfully removed.¹

Whatever the origin of these cysts, they appear, on the one hand, independent of any tooth-irritation; and on the other, of any previous cartilaginous deposit. The diagnosis in such cases is not beset with much difficulty; and even if a doubt exist as to the nature of the tumour, it is at all times safe and easy to explore it with a trocar.²

In the treatment of these tumours, it is a milder and a more justifiable course to make a free incision into the cyst, and subsequently to trust to reparative action, than at once to have recourse to removal of the diseased mass.

If the cyst be large, or even if it be ultimately requisite to remove it in its entirety, the previous incision will in all probability have much reduced it in size; when the parts, if not in a better, will certainly be in no worse, condition for removal.

In both the cases related removal of the tumours was accomplished without difficulty. Two cases are mentioned by Paget, in which incisions were employed successfully; but in neither case did the bone appear diseased.

In a case under the author's care in St. George's Hospital, the cyst occupied a large portion of the left side of the upper jaw. Its anterior wall projected under the cheek, and bulged out the side of the face. A free incision was made into the cyst from within the cheek. The anterior wall was found to be partly membranous, and partly consisted of thin flakes of bone. A portion was readily removed, so that a free opening was left for the escape of the contents, which were of a glutinous consistence and brownish in colour. At the bottom of the cyst there was found projecting into its cavity the extreme point of the fang of the canine tooth. On the removal of the tooth, the fang was found to be partially necrosed. The cyst contracted and closed in a short time without any further treatment. The patient was about ten years of age, and when he quitted the hospital there was no trace of the disease left, nor the slightest disfigurement.

In all cystic diseases of the jaw, careful examination should be made of the teeth, all diseased ones near the growth should be at once removed. One of the most frequent causes of serious mischief, and still oftener of exquisite suffering, is the too long abode of defective and decayed teeth in their sockets. We feel satisfied that the greater the experience in the treatment of diseases about the mouth, the more exacting will the surgeon become respecting the removal of all useless, defective, or decayed teeth or stumps.

Fibrous tumours of the upper and lower jaw are by no means uncommon; and in their general features, in their growth, and in their varieties, correspond to fibrous tumours of other parts. 'The favourite seats of fibrous tumours of bone and periosteum are about the jaws.'³ Such tumours may originate in the substance of the bone, and in growing, expand it, as a crust, over the outer surface of the tumour. In the Museum of the College of Surgeons there is a preparation showing a fibrous tumour of the jaw, with a thin shell of bone over it.⁴ They may grow from the periosteum, and embed the bone in their surrounding mass. They affect equally the upper and the lower maxilla. They may appear early in life.

¹ Museum Catalogue, No. 1033.

² M. Giralde's has described a form of cyst in connection with the upper jaw, which he believes to be of very common occurrence, and to be formed by a morbid change in mucous glands naturally existing in the lining membrane of the antrum of Highmore (see his *Recherches sur les Kystes du Sinus maxillaire*); but no such origin can be ascribed to those which distend the body of the lower jawbone in the manner above described.

³ Paget, vol. ii. p. 145.

⁴ No. 1045.

Mr. Liston removed a large fibrous tumour of the upper jaw, in a woman twenty-one years of age, which had made its appearance four years previously.¹ It grew on the outer side of the jaw, and was removed six months after its first appearance, when about the size of the end of the thumb. In eighteen months a return of the disease, the size of a hen's egg, was removed, with a portion of alveolus. The growth reappeared in two or three weeks, and attained a large size in two years, which rendered necessary the removal of the whole of the superior maxillary bone. The patient recovered.

Fibrous tumours of the jaw are usually of rather slow growth; but their growth may in exceptional cases be somewhat rapid. Their usual history is one of progressive and persistent increase; perhaps more rapid in proportion to their increase of size, but, in the main, rather slow than rapid. The size some will attain is best illustrated by the collections in our various museums; and especially the preparations collected by the late Mr. Liston, now in the possession of the College of Surgeons. In some respects, as to the size which they attain, they appear to vary from fibrous tumours of other parts, and especially those of the uterus; for fibrous tumours of the jaws are not usually seen to expend their energies in growth; they are not seen to stay their course, to degenerate, or calcify; or perhaps something may be said to depend on their position, for this is such that it can never permit of sufficient increase, or life, to attain that end, without first having grown to such a size as to occasion fatal impediment to deglutition or respiration. They are usually painless in their growth, and innocent in character, as compared with cancer; but their locality as they grow renders them formidable as to disfigurement, as to discomfort, and even ultimately to life, if they be not removed before such growth be attained. It is wise, therefore to pass the verdict of early removal, when we have to pronounce judgment on such cases; the earlier the operation is performed, the less formidable will it be. We cannot hold out a prospect of arrest; but we may certainly forewarn as to the inconvenience of delay, and we may positively predict danger from increase, and at the same time offer some relief to the sufferings of the patient. An especial reason for early removal applies more to tumours connected with the upper than to those of the lower jaw. The tumour which commences in the antrum, or any other part of the superior maxilla, will constantly be found by pressure to cause the absorption of the floor of the orbit, and then to make its appearance in that cavity. By degrees the latter becomes filled by the growth, while its original contents are destroyed and absorbed. The eye itself is early sacrificed. Still expanding, the mass presses on the upper wall of the orbit, and in time surely gives rise to its perforation, in a manner similar to that observed in the wall of the antrum, and thus is ensured the contact of the growth with the surface of the dura mater. When such a complication is established, removal of the tumour is one of great hazard, if not certainly fatal.

A man was admitted into St. George's Hospital, under the care of the author, with a large fibroid growth projecting from the antrum and entirely occupying the cavity of the orbit. The eye had long been completely destroyed. There was not much doubt about the practicability of removing the mass with the whole of the left superior maxilla; and as the patient was anxious to be rid of the sufferings entailed by the presence of the growth, the author removed it without difficulty. The tumour had apparently originated in the antrum, but had no attachment to the sides or upper wall of the orbit, though the cavity was not only filled, but was also much expanded by the growth. The patient bore the operation fairly well. The whole of the left superior maxilla was removed, and with it the tumour in its entirety. Symptoms of meningitis soon set in, and the patient died in a few days. On examination after death, the upper wall of the orbit was found perforated in two places, and hence the origin of the meningitis.

In their structure we cannot point out any distinction between the fibrous tumours which attack the lower, and those found connected with the upper jaw; but, practically, there are some important considerations connected with the history of the latter to which we would especially draw attention; and a knowledge of which is most essential to any operator dealing with such cases. Fibrous tumours

¹ Museum of College of Surgeons, No. 1046.

of the lower jaw are invariably more or less globular in form; usually they have a uniformly smooth surface; their tendency is to protrude externally, more than towards the mouth: if originating in the substance of the bone, perhaps they may be found equally surrounding it; if originating in the periosteum, perhaps most prominent on the corresponding surface. Fibrous tumours of the upper jaw are often far different in their outward character, in their surrounding relations, and in the tendency they display, from position, to spread in different directions. A fibrous tumour supposed to be attached to the upper jaw may really have its origin from the base of the skull, the sphenoid, or the ethmoid bone, and from either point make its way through the various foramina and fissures, and into the various fossæ in and around the superior maxilla. Instead of a globular dense mass, as in the lower, the tumour of the upper jaw may be lobulated; or, from its very position, and as a result of its insinuation into these fissures and fossæ, it may be moulded, as it were, into a mass of pedunculated bodies, somewhat analogous to the bulbous roots of a tuberous plant; or, commencing in the interior of the antrum, it may by growth or position be pressed through its anterior wall, and puff out the cheek; or through its floor, and push down into the mouth, or into the nose, and plug up the lachrymal duct; or into the orbit, and displace the eyeball, or into all or several of these spaces, and produce corresponding deformity. So that the diagnosis of the origin of a fibrous tumour of the upper jaw is often as complicated an affair as that of the lower is easy; indeed in some cases, until the upper jaw be removed, it will be impossible to determine to which portion of the skull, or bones of the face, the growth may be attached.

The following case illustrates the force of these observations. A man twenty-five years of age was admitted into St. George's Hospital, under the care of Mr. Prescott Hewett, 'with a large tumour, of an irregular shape, occupying various regions of the left side of the face.' In the cheek it formed a swelling of the size of a turkey's egg, and filled up the greater part of the superior maxillary region: the outline of the bone was perceptible to the touch in a few places only; the zygomatic arch was much more prominent and more curved than natural, having been pushed forward by the tumour, portions of which could be felt under the temporal muscle. The diseased structure was also found, in the shape of small flattened bodies, at the lower part of the orbit, lying immediately underneath the conjunctiva, and apparently quite movable; the bones of the inner and outer walls of this cavity, as well as those forming its circumference, were not affected or displaced, but it was impossible exactly to make out the state of the bones at the lower wall, owing to the tumours which were there, the eyeball was not more prominent than natural. Portions of the morbid growth were detected in the left nasal fossa, from whence a small round mass projected slightly, at times, into the pharynx. The tumour overlapped the front part of the alveolar process, and projected beneath the lip.

About six years previous, the patient had observed what was supposed to be a polypus of the nose, which was easily removed; but some little time after the cheek began to swell, and gradually the tumour commenced to show itself in the various other positions described. Its growth was painless throughout. A year previous, caustic had been freely applied, with the idea of destroying it; and two large cicatrices marked the places of its action. At various times there had been extensive bleeding from the nose; these bleedings had somewhat reduced the patient, who was of a spare habit and pale, this paleness being attributed to a loss of blood which occurred shortly before his admission. It was decided to remove the tumour by the usual incisions for the removal of the upper jaw. The bones having been divided with cutting forceps, the superior maxillary and malar were easily tilted out of their place, when it was found that the disease was not connected with the upper jaw, but was behind it. The greater portion, which was in view, was removed; some portions were lying in contact with the pterygoid process; some portions embedded under the temporal muscle; other portions in the orbit. Before the operation could be completed, the patient became so faint that it was found impossible to proceed with the operation, and he subsequently sank.¹

The preparation of the parts shows the superior maxillary and malar bones, and portions of the tumours extracted from behind them; the bones are healthy, but altered in shape from pressure; the tumours present all the characteristics of fibrous structure. The parts removed after death show a morbid growth, originating in the root of the left nostril, and especially on the inner edge of the pterygoid process and under surface of the body of the sphenoid bone, to which parts small portions of tumour were found still attached. The sphenoidal sinuses were filled with diseased structure of a similar character, and were very much dilated;

¹ *Med.-Chir. Trans.* vol. xxxiv. p. 43.

so much so, that at one point the bone had been altogether absorbed, and in its place was a small hole, where the tumour was lying in contact with the dura mater. A small portion of the growth was also found at the upper and back part of the septum nasi, which was forced over to the right side and partially destroyed by absorption: here the mucous membrane was somewhat thickened; and there was a small pendulous body, loosely connected to the velum palati, and hanging by the side of the uvula. Small flattened growths of a similar nature, and of a bulbous shape, were found deeply embedded in the spheno-maxillary and temporal fossae, as well as at the back part of the orbit. None of them had any attachment to the bones; they were all connected to each other and to the growths in the nostril by a slender pedicle, which passed in the direction of the spheno-palatine foramen: the growth in the orbit had reached that situation by creeping through the spheno-maxillary fissure. The bones of the orbit were quite healthy. The preparation is in the Museum of St. George's Hospital.

The removal of a fibrous tumour with the entire portion of the jaw with which the growth is connected does not necessarily ensure an immunity from recurrence. Two specimens in the Museum of the College of Surgeons illustrate the reproduction of a fibrous growth, subsequent to the removal of a previous one.

One preparation shows the right side of the lower jaw, from the angle to the first bicuspid tooth, with a tumour of a fibrous character, two inches in its greater diameter, and situated entirely on the anterior surface of the bone, and extending along nearly the whole portion removed. Its base is osseous, and the rest fibrous.¹ The other shows the ascending ramus, condyle, and coronoid process of the lower jaw, with a tumour of a similar character.² A woman thirty years old had suffered from 'toothache' from nine years of age, after a blow on the cheek. The first portion of the jaw, with the tumour, was removed about five months after it was first observed; its growth had been painful, both in the jaw and the cheek, and was attended by constant headache. No portion of the disease was apparently left at the first operation. But the disease reappeared at the ramus, which was subsequently removed at the joint. The patient recovered.

Subject to this occasional tendency to recurrence, fibrous tumours may be classed as essentially innocent; largely so, in proportion to many of those which affect the jaws; if by the term innocent we intend to convey the possibility of complete eradication by operation, and, subsequent thereto, a total immunity of the part and the system from recurrence of the disease.

And yet, as in other parts, so in these, we must be prepared to meet with fibroid tumours which present many of the characteristics of true fibrous growths, but possess in addition the peculiar property, that upon each removal there appears a more rapid tendency towards recurrence, as well as greater rapidity in growth; from the true structure of fibrous tissue, as each removal takes place, there is a gradual shading off into fibro-plastic or mere gelatinous tissue; until at last rapid growth and rapid deterioration of constitution run hand in hand, and the patient sinks, exhausted by a foul ulcerating sore based on a monstrous fungoid mass. When cut into, this mass presents a smooth, gelatinous, and somewhat elastic surface: the structure abounding in serosity, and often readily breaking down; void of many blood-vessels, and of a low vitality.

Fibrous tumours of the jaw may be partly composed of bone; or partake of a fibro-cellular character, such as we find in similar tumours of other parts of the body. In the Museum of St. George's Hospital is a preparation showing, on section, a small nucleus of bone which in no part approaches the surface of the tumour.³ Another specimen shows much bone radiating into the substance of a fibrous tumour from its base, and approaching in some parts very near the surface.

Fibrous tumours, usually of slow and painless growth, are often attended by suffering when they affect the jaws; and their growth may be sufficiently rapid to require the aid of the surgeon within a few months of their outset to obviate the serious results of pressure and encroachment on the cavity of the mouth.

'As a general rule the vascularity of a fibrous tumour is in inverse proportion to its singleness and toughness of construction.'⁴ Yet, in the region of the mouth, we constantly observe a tendency to recurring hæmorrhage, to be attributed in some measure to the friction the surfaces may be subject to, or the accidental bruising they

¹ No. 1041, College Museum.

² Series ii. No. 155.

³ No. 1042, *ibid.*

⁴ Paget, *op. cit.* vol. ii. p. 134.

may receive, in the daily process of mastication. This hæmorrhage is not usually very great at any one time; but it has this important practical bearing, that by its amount or by its frequency it deprives the patient of much blood; he becomes blanched and reduced; and if relief be long deferred, he becomes little capable of undergoing an operation, which of itself often exacts the immediate loss of a large amount of blood. A case already related points to the principle here enunciated.

Myeloid tumours of the jaws.—What has already been said relative to the general features of fibrous tumours originating in the jaws will to some extent apply to myeloid tumours affecting these bones. They will perhaps be found to affect those parts almost as frequently as the fibrous tumours. The Museum of St. George's Hospital contains several specimens of myeloid growths connected with the maxillary bones.

The general characteristics of these growths have been well summed up by Paget. 'Myeloid tumours,' he says, 'usually occur singly; they are most frequent in youth, and very rare after middle age; they generally grow slowly, and without pain; and generally commence without any known cause, such as injury or hereditary disposition. They rarely, except in portions, become osseous; they have no proneness to ulcerate or protrude; they seem to bear even considerable injury without becoming exuberant; they may (but very rarely) shrink, or cease to grow.'¹

A specimen in the Museum of St. George's Hospital shows a tumour about the size of a nut, with a portion of the whole depth of the lower jaw, which was removed from a girl eight years of age. Four and a half years after, she remained well.² Mr. Cesar Hawkins removed a tumour of a similar nature, with a portion of the alveolus of the upper jaw, from a little girl five years of age, in St. George's Hospital. This had grown rapidly in the course of about three weeks, and was successfully removed.

The diagnosis of a myeloid tumour is always uncertain without microscopical examination of its structure. In its origin and growth, in connection with the jaws, it may be mistaken, as in all other parts which it attacks, for cartilaginous or fibro-cellular growths. Its characteristic features are most marked in its intimate structure; for an account of which we refer the reader to the essay on TUMOURS, vol. i. p. 273.

The nature of myeloid tumours of the jaw permits of no half measures in treatment; entire removal of the growth, with the portion of bone to which it may be attached, is the only safe, the only justifiable course to be pursued; and no delay should be recommended or sanctioned. As it will surely grow large when once started, it should without hesitation be removed whenever detected. The removal does not always insure safety. There is no doubt that myeloid disease is sometimes recurrent. The experience of late years has fully established this fact.

A patient under the care of the author was the subject of a myeloid growth affecting the left side of the lower jaw. Some seven years previously she had been operated on for a similar growth in the same situation. The original mass appeared to have been freely removed with a portion of the alveolus, but had been gradually returning for twelve months. This was removed by the author with as much bone as appeared to be implicated, and, as far as could be ascertained, no diseased portion was left behind, but the entire depth of the bone was not included in the removal. In the course of about three years a tumour again showed itself in the old place; and nothing remained but to remove the greater portion of the left side of the jaw. There has been no return in the lapse of five years. The mass removed was true myeloid.

Osseous tumours of the upper and lower maxillæ are not very commonly met with, but occur sufficiently often to make them especially interesting in connection with the surgery of the mouth. They will be found to occur in two different forms or characters: simply as outgrowths from the parent bone, to which a base more or less narrow or broad is attached; or as a general thickening and enlargement of a part, or of the entire bone, terminating often in considerable and even frightful malformation.

¹ *Op. cit.* vol. ii. p. 217.

² Series ii. No. 168.

The true osseous tumour is often compact, heavy, hard, and ivory-like on section ; or else more spongy or cancellous, much less hard, and much less weighty in proportion to its size. Practically, the size, the rapidity of growth, and the locality, are of more importance than the exact condition of its structure.

Osseous tumours are seldom rapid in growth ; they may affect any portion of the jaws ; they are not usually painful, but generally and steadily increase in size, and sooner or later their removal is rendered imperative.

In the Museum of the College of Surgeons is a preparation which shows the true character of the hard ivory-like tumour of the jaws. It is seen growing from the angle of the lower jaw, to which it has an attachment by a broadish base.¹ Another similar specimen may be seen in the Museum of St. George's Hospital.² The removal of these outgrowths, whether they implicate the upper or lower jaws, presents no greater difficulties than does the removal of fibrous or other tumours ; excepting, that if deeply nodulated and irregular on the surface, they may be entangled in the fibres of the adjacent muscles, and require much careful, it may be tedious, dissection, before they can be cleared from the surrounding soft parts.

There remains to be considered the other condition referred to, in which the bones of the face, or any portion of them, take on a peculiar process of growth, thickening, and occasionally great enlargement.

The Museum of the College of Surgeons contains specimens illustrative of this diseased action in bone, and they demonstrate what an amount of hideous deformity may occur in the victims of this horrible disease — horrible, inasmuch as it appears perfectly beyond the control of medical treatment ; and unless seated in a part readily removable, entails on the wretched sufferer a lingering malady which, though slowly, yet surely, in most cases, continues its growth until its mechanical interference with the process of deglutition, or some other complication, causes death.

The tendency of this disease appears to be, that it does not restrict itself to one bone, or one portion of a bone ; but that several bones contiguous to each other may become affected in their turn, and to such an extent that all surgical interference would be quite out of the question. If, however, the disease be confined to one portion of the face, such as the lower jaw or the antrum, it may probably be relieved by operation.

This diseased action may be set up in very early life. A case is related by Paget, in which Mr. Stanley removed the superior maxillary bone in a girl, fifteen years of age, in whom the swelling had been observed to commence eight years previously.

With respect to treatment of osseous tumours generally, it will be found, as a rule, that neither local applications nor constitutional measures appear to arrest, or destroy their growth. It is but a waste of time, and trifling with the patient's confidence, to suggest anything but the entire removal of the tumour. Of course this recommendation will depend on the amount of bone implicated by the disease ; but if the mass can be *entirely removed* by the knife and saw, and the operation be otherwise practicable, the removal of the tumour is most likely to be perfectly satisfactory in its results. It may be stated that absolute security against the reproduction of an exostosis can be obtained only by the removal of every part of its circumference. If but the smallest portion of the exterior of the exostosis, with its cartilaginous capsule, be left, reproduction of the tumour will be, at the least, not an improbable occurrence.³

Experience has fully confirmed the observations just quoted ; and the caution which they inculcate is, not to attempt the removal of a portion, when the whole mass of an osseous tumour may present obstacles to its entire resection. How far the hypertrophied condition of bone may hereafter prove to be subject to constitutional treatment is a fair question of experiment. The disease is not common, and opportunities are few in which the efficacy or benefit of drugs, externally or internally, can be fairly tested. The disease has certainly something more of a constitutional character than simple osseous outgrowth, and the condition is one which has been known

¹ No. 1035.

² Series ii. No. 191.

³ Stanley, *On Diseases of Bones*, p. 157.

occasionally to assert the prerogative of hereditary transmission. In reference to treatment, Mr. Stanley states that 'medicines have no influence upon the disease.'

In their removal by operation, there is an exception to the rule which applies to osseous tumours, that the whole of the disease must be removed; for when the deformity is the result of hypertrophy, if the whole mass is beyond removal by the surgeon, even a portion may be cut away with present if not permanent benefit. 'I know, in cases where only part of the hypertrophied bones have been removed, the wound has healed soundly over the remaining portion of them; and it has not in such instances appeared that the operation was followed by any increase of the disease.'¹

Vascular tumours of bone are so rare, and of the jaw so few instances have been placed on record, that we even venture to express some hesitation in taking for granted that those described may not have been tumours of a cancerous nature. The entire removal of the disease is the only treatment to be recommended. As described, the disease appears to commence in early life, and to be painless; but its external characters are such that no very accurate opinion can be formed of its nature, unless it present on the surface the deep red colour produced by enlarged vessels.

Mucous tumour, or myxoma.—Virchow has drawn attention to this variety, and it will be found described in the essay on Tumours (vol. i. p. 267). They are rare in the jaw, but have been met with. They may be removed like other tumours, and are not liable to return.

Cancerous tumours of the maxilla, and cancerous ulceration of the gums, remain to be considered.

Cancer of the bones of the mouth is by no means uncommon; it is generally of the medullary form, occasionally of the osteoid variety. Cancer of the gums is more rigidly confined to the epithelial character. Scirrhus, in its onslaughts, appears to disregard these regions; for though found as a secondary condition in bone, it has not fallen to our lot to notice it in the bones of the face; the experience of others confirms this observation.

Cancerous growths are observed more frequently to affect the superior than the inferior maxilla, and to commence most frequently in, or around, the walls of the antrum. The history during life, and the anatomy, of medullary and osteoid cancers of bone, written elsewhere in this work, apply in every minute particular to the origin, the growth, and the structure of cancers affecting the bones of the face. It is not, therefore, requisite to enter now into a minute examination of their constituents; our remarks will embrace the chief practical features to which the attention of the surgeon should be directed, so that a correct diagnosis be arrived at, and prompt measures adopted where necessary.

Age is no criterion, in the diagnosis to be formed, respecting a cancerous tumour of the mouth. We observe the disease in children, in persons of middle life, in the extreme of old age. It commences often without pain, but it rarely progresses without suffering; and in many instances the pain of cancer affecting these bones is severe beyond description. The external appearances of these tumours differ in many ways, and much in each case.

The diagnostic point, however, which always marks the difference between a non-malignant tumour and one of a cancerous nature is the more easily implication and contamination of the tissues which surround the latter; the adhesion of the skin externally, and its frequently brawny dark red and congested state being marked, especially on the surface of those which protrude much outwards.

When the disease is confined to the lower jaw, its character may be more readily and earlier detected than in the upper. If medullary, it displays a softish pulpy mass, more or less elastic; projecting, it may be, on the outer side, and bulging out

¹ Stanley, *On Diseases of Bones*, p. 5.

the chin or cheek ; or on the inner side, and pushing down towards the throat ; or it may uniformly surround the bone.

A case illustrative of the later condition was (1863) in St. George's Hospital, under our care. It was rapidly running its course. The patient, a man aged 40, observed a swelling on the outer side of the lower jaw four months previous to admission. The tumour rapidly increased, and, on admission, involved the bone, from the symphysis to the first molars on each side. It projected backwards and downwards to the hyoid bone. The skin over it was stretched, and partially adherent, especially at the lower and left side, where it was thin, soft, red, and pulpy ; much as if the disease had nearly made its way to the surface. Some of the teeth on the left side were becoming prominent and loose. Under such conditions, it was thought best not to interfere by operation. The patient died about three months after his admission.

Occasionally the masses which project into the mouth run early into ulceration, discharge very offensive matter, and often have a ready tendency to bleed. If teeth become loose and are removed, a fungoid growth shortly fills the vacant alveolar sockets. The external parts, if the tumour projects externally, appear soon to become thoroughly implicated in the growing mass ; the skin becomes bound down to the parts beneath ; it becomes darker coloured, dusky red or purplish ; brawny, uneven, and puckered, with soft round knobs projecting outwards ; and ultimately ulcerated, when rapid destruction of structure sometimes occurs from sloughing. A foul excavated and irregular sore is thus produced. The neighbouring lymphatics frequently bear evidence of the constitutional contamination ; and the cachexia of cancer is usually well marked.

When the upper jaw is the seat of cancerous growth, there is often, in its early stage, some difficulty in arriving at a correct diagnosis as to the nature of the tumour. It is often but little exposed to view ; it may be entirely embedded in an osseous chamber ; or compressed and moulded by osseous walls, which, in the commencement, retard or direct the course of its growth. It may project into the nostril, block it up, and, perforating the septum, pass through to the opposite side ; it may commence in the anterior wall of the antrum, and project forwards under cover of the cheek ; or from the outer wall, and proceed downwards over the alveolus, and upwards into the temporal fossa ; or from the interior of the antrum, and make its way uniformly into the nares, into the mouth, into the orbit, outwards, and forwards, and backwards. As it grows, the bones adjacent to it become expanded to some extent ; then implicated or absorbed. If it presses forwards, the cheek and upper lip become distended and puffy ; the fungoid growth within increases, and protrudes sometimes, at the angle of the mouth ; the eyelids become œdematous, and by degrees are closed ; or perhaps, prior to this, the eyeball is pushed forwards or outwards ; and the cornea, no longer covered by the lids, ulcerates or sloughs, and the contents of the globe escape. Nothing can be more hideous than the advanced condition of a medullary cancer of the upper jaw, presenting often a mass half as large as the head itself ; ulcerated or sloughy on its surface ; discharging horribly stinking pus, mixed with blood ; and persecuting the sufferer with unabating and often agonising pain.

Rapidity of growth is a strong point in the chain of evidence which is to decide the character of such tumours. But we have already observed, that rapid growth is seen occasionally in tumours of a non-malignant character. In medullary tumours rapid growth is the rule ; early attainment of size a marked feature ; and the rapidity of growth commensurate with increase of size. The constitutional deterioration also is continuous. The early contamination of the skin with the tumour should surely point out to the surgeon the extreme foolhardiness of attempting to remove a mass of disease, the extent of which it is almost impossible to define ; and, consequently, the satisfactory removal of which is rarely practicable, with due regard to the patient's best fit.

To illustrate the various points herein put forward, and to mark especially the difficulty of obtaining a satisfactory insight into the origin of such growths, as well as to indicate the utter hopelessness of attempting to remove many of them by operative interference, we wish to draw particular attention to the following cases :—We were consulted by the parents of a child, L. C., aged 5, suffering from a tumour, supposed to be connected with the upper

maxilla of the left side. The left nostril was filled up and pushed outwards; the soft palate was much pressed downwards, and a portion of the tumour could be seen at its lower edge. Some attempts had previously been made to drag away the mass; but upon each occasion alarming hæmorrhage occurred. As the disease was evidently medullary cancer, increasing rapidly, and there was great uncertainty as to its origin, it was recommended that no operation should be permitted. The child died within two months of our first visit.

The face was greatly disfigured by considerable protrusion of the left eyeball outwards and forwards, by the expansion of the nostrils, and by the projection of a fungoid mass from the left one.

The dura mater, between the sella turcica and the ethmoid bone, was thickened on its attached surface, and readily separated from the bone. The corresponding portion of bone, as well as the cribriform plate and crista, were more vascular, darker coloured, and less compact in structure than natural. The nostrils were filled with a whitish medullary tumour. It had projected in front to such an extent that it had separated the nasal bones and cartilages some distance from each other. Inferiorly, it had partially protruded through the

FIG. 130.—Portrait of a patient with Malignant Tumour of the Upper Jaw, and deficiency of the Lower Jaw.

anterior orifice of the left nostril, and had separated the palate processes of the superior maxillæ and palate-bones sufficiently to admit the point of a finger between their edges. The septum nasi was absorbed to a great extent, also the inner walls of the orbits; and thus the tumour projected into the cavity of each orbit, occupying the whole of that of the left side, where it had pushed the eyeball outwards, on a level with the anterior orbital margin. The tumour had also penetrated into each antrum. Posteriorly it had passed through the openings of the posterior nares; was in close contact with the under surface of the basilar process and the anterior surface of the upper cervical vertebra; pressed down the soft palate considerably; and had extended into the pharynx almost as low as the epiglottis.

The above case illustrates the progress of medullary cancer of the upper jaw in childhood; the following shows how similar are the conditions in more advanced life; and both show how in each the surgeon would be foiled in any attempt to remove them. A woman aged fifty was admitted into St. George's Hospital in July 1861, under the author's care, for a tumour apparently growing from the antrum, and involving its anterior wall and the hard palate. Five months previous she had a decayed tooth removed from the upper jaw, for pain

on the left side of the face and head; immediately after which the gum enlarged, and an abscess which formed was opened, when the escape of about half an ounce of pus took place. The opening closed; but as the swelling returned, it was again lanced two days after, but on this occasion no pus escaped. From that time the swelling continued to increase, and now presented a prominent mass over the antrum and in the mouth, both in front of the alveolus and through the hard palate. The tumour grew very considerably. She suffered excessive pain. The eye, pushed forwards, became opaque, and sight was soon completely destroyed; deglutition also was difficult. She died about ten months from the commencement of the disease.

The skin was not implicated in the growth. The bones surrounding the mass were so soft, that they were readily cut with a scalpel. The tumour projected largely into the mouth; it involved the palate, the inferior turbinated, the ethmoid, the sphenoid, and the superior maxillary bones. Through a portion of the ethmoid and sphenoid bones there was an opening communicating with the cavity of the skull. The growth, with the portion of upper jaw that remained connected with it, is in the Museum of St. George's Hospital.¹

H. W., aged 38, was admitted to St. George's Hospital under the author's care, January 1870. In July 1869, she first noticed swelling of the right lower eyelid, with neuralgic pains over the right temple and brow. After a month the eye began to protrude. In September the right cheek began to bulge out, and the right side of the nose to enlarge. The sight of the right eye had been failing for some two months prior to her admission. The mass now (April 1870) projects into the right nostril, into the right orbit, and outwards under the cheek and masseter; and bulges into the mouth to a slight extent. Hemorrhage occasionally occurs from the nostril. The increase of the tumour is very perceptible; its aspect is represented by the engraving.

The peculiarity of this patient's condition is, that *she has no vestige of a lower jaw*. It is related by her friends that when two years of age the lower jaw exfoliated entirely; but there is now no indication of such a bone having ever existed. She has always been fed on soft food.²

If a cancerous tumour of the lower jaw be seen in an early condition, if it is situated near the symphysis, and the patient desire it, its removal, with the whole depth of the bone to which it is attached, may be attempted; for if situated in front, the limits may be ascertained, and the tumour dissected out entire. But if it involve the bone near the angle, we can seldom ascertain how deeply it may extend, or to what degree it involves, by infiltration, the tissues at the root of the tongue; it may extend far beyond the reach of the scalpel.

After all, it will be found that much discrimination is required on the part of the surgeon who has to decide upon the removal of a cancerous growth of the jaw; so much depends on the individual features of each case, that it would be entirely out of the question to attempt a strict code of directions relative to treatment. At best, however, interference by operation is in the large number of cases most unsatisfactory: in the few, we hope some benefit is conferred.

We cannot do greater justice to the subject than by transcribing, in conclusion, the words of Monsieur Giraldez: 'Dans le traitement des tumeurs du sinus maxillaire, il est des cas dans lesquels le chirurgien doit agir, et d'autres cas dans lesquels il est prudent de s'abstenir. Lorsque les tumeurs sont de petit volume, et surtout lorsque la constitution du malade n'est pas altérée, l'art doit intervenir, et dans ce cas, il peut arrêter le mal pendant quelque temps, et prolonger la vie des malades. Si la tumeur est volumineuse, sans que la constitution du malade soit encore altérée; si la cachexie cancéreuse n'est pas développée, le chirurgien doit encore intervenir, et par deux raisons: d'abord, parce qu'il peut arrêter pour quelque temps la marche d'une maladie qui a une grande tendance à progresser; ensuite, parce qu'il peut avoir affaire à une tumeur fibro-plastique dont la malignité, dans le cas où elle serait maligne, serait toujours moindre que celle des tumeurs encéphaloïdes. Lorsqu'enfin la tumeur du sinus est volumineuse, qu'elle envoie des prolongements en tout sens, que la constitution du malade est altérée, l'intervention de l'art ne ferait que compliquer un état déjà trop grave.'³

The gums and the other soft tissues of the mouth, if affected by cancer, are usually attacked by the epithelial variety. Commencing gradually on the surface of the former, it runs its course, similar to that species of cancer elsewhere. By degrees the ulcerated surface spreads; the borders of the ulcer present their usual thickened and elevated edges; not only the cheek, but the floor of the mouth and tongue become secondarily affected. The disease in this situation is generally very painful;

¹ The author is indebted to Mr. Charles Hunter for the post-mortem examination.

² The patient died soon afterwards.

³ *Des Maladies du Sinus maxillaire*, p. 54.

much distress is occasioned by movements of the cheek or tongue ; much misery entailed by constant escape of saliva ; great inconvenience and often difficulty is experienced in articulation and mastication.

Epithelial cancer affecting the mouth appears to partake of a more malignant aspect than it assumes elsewhere ; or rather, we might say, its local position renders it an obstacle to the requisite supply of food ; consequently the life of the patient is sooner terminated. The glands in the sub-maxillary and cervical regions will often be found to be early implicated in epithelioma of the mouth ; under such circumstances operative interference would not be justifiable. But should the condition of the patient, with the absence of gland enlargement, and the situation of the disease, indicate any hope of relief from an operation, the surgeon must exercise his judgment in deciding to carry it out. As a rule, however, the results are not satisfactory. The treatment to be adopted locally should consist of gargles, to obviate the distress occasioned by offensive discharges ; constitutionally, anodynes to hush the pangs which constantly dart through the parts affected.

OPERATIONS.

As operations for the removal of the lower or upper jaw, or any portions of them, have been fully described in all treatises on Operative Surgery, we feel that there is nothing new to record in the following observations. Our notice of the diseases of the jaws would, however, be incomplete were we not to lay before the reader the general rules he should observe, and the manner in which he should proceed, when called upon to operate on either of these bones.

Operations in diseases of the lower jaw may involve the removal of but a small portion of the bone ; of a large portion of its anterior division ; of one half—from the symphysis to the condyle ; or rarely of the whole bone, with both articular processes. There is considerable difference in the method of proceeding under these various conditions, but chiefly as regards the external incisions required in each.

A small tumour may occupy only a portion of the anterior part of the lower jaw, and the growth be found connected with the alveolar edge without affecting the bone to a greater depth ; extending perhaps further laterally than downwards. It may have involved the alveolar process to such an extent, that the corresponding teeth are loose or have been pushed out. A case in which a tumour (fibrous) affected the lower jaw to the extent of the four incisors, came under our care a few years ago. The tumour was firm and painless, and involved about half the depth of the jaw. The canine teeth were removed ; a saw was then used to cut down on each side of the tumour, through half the depth of the bone ; then, with a pair of cutting forceps, the upper half of the bone, between the lateral cuts, was taken away with the tumour still adherent to it. Sir W. Fergusson relates a case in which he removed a much larger portion, in breadth, of the lower jaw, by a similar operation.¹ He justly observes, that the advantages of being able to leave the lower half of the bone are very considerable ; for the lower jaw retains its shape, and false teeth can be readily adapted to it when the parts are healed. When, under these circumstances, the tumour is small, no external incision is requisite. In the case alluded to, Sir W. Fergusson was obliged to expose the tumour by making incisions from the angles of the mouth to the base of the lower jaw. If the operator can possibly avoid cutting through the lip, he should by all means do so ; and it will be found that, by drawing the lower lip down, separating it from the bone, and with retractors pulling upon the angles of the mouth, a considerable surface of the anterior part of the bone may be exposed, without any external incision. Instead of two incisions through the lower lip, when a tumour has to be removed with the anterior portion of the jaw, one incision in the median line may suffice : it can be carried down below the chin without any obstacle or objection ; and this allows the flaps to be drawn well over to either side, so as to expose a considerable portion of the bone. The downward

¹ Fergusson's *Practical Surgery*, p. 668.

extension of the incision also affords a ready escape for the future discharge from the wound.

When a tumour involves the whole depth of the bone, and this has to be removed with the morbid growth, the external incisions having been made, the flaps must be cleanly dissected from the tumour, to expose a sufficient surface of healthy bone on each side. In order to enable the surgeon to cut where the tissues are sound, the teeth should be removed where the bone is to be divided. The anterior surface being denuded, the posterior has to be freed from attachments of muscles, &c. Prior to passing the knife behind the bone, the tongue must be secured; a strong ligature should be passed through its apex, and held by an assistant. Of course this is only requisite when the muscles are detached at the symphysis. If this precaution be neglected, the tongue is apt to fall back on the division of its muscles, and the patient runs the risk of suffocation. The ligature may be removed a few hours after the operation; in the meantime it should be held by an assistant, or otherwise secured on the face. A large fibrous tumour of the lower jaw was removed in our presence, with more than half of the bone, without any attention being paid to the tongue; the patient appeared choking, when the tongue was seized with a pair of forceps, drawn forwards, and immediately secured with a needle and thread, and the patient again breathed with comfort. If the tumour be very large, and irregular on its posterior aspect, it is better first to cut through the jaw, and subsequently to detach it with the tumour. The isolated portion of the jaw can thus be turned forwards, and the mass dissected from the soft tissues at the floor of the mouth, commencing within from above downwards. The method of dividing the jaw is simple, if properly performed. The outer shell of the bone should be notched with a fine saw, and then the bone cut through with a pair of strong bone-cutting forceps. When a tumour implicates the side of the lower jaw, or runs near to or involves the ramus, the external incision, to expose the bone, should differ from that described. If it be requisite to disarticulate the bone, the external incision should commence just above and over the corresponding temporo-maxillary joint; be carried down to near the angle; then turned forwards to the side of the chin and (if the tumour extend far forwards) towards the border of the lip, and terminate within a little of its free margin. The integuments of the side of the face included in this line of incision are now to be dissected upwards. The incision has crossed the facial artery; and as the flap is dissected off, the artery must be divided; it had better at once be tied, to save loss of blood. The bone immediately in front of the diseased mass has then to be divided, as described. The portion to be disarticulated must now be seized and drawn outwards; some force may be requisite to effect this. As the bone is drawn outwards, the mucous membrane and muscles are to be detached from its inner surface. The knife has only to be kept in close contact with the bone to effect this, and to avoid all unnecessary danger. As the articulation is approached, the bone should be still pushed forcibly outwards; the point of the knife made to cut close to it, and care taken, in cutting through the ligaments of the articulation, not to let the point be carried inwards, or out of sight. The external carotid or the internal maxillary may readily be wounded, if this precaution be neglected. If disarticulation be not requisite, in consequence of the tumour not extending to the condyle, the external incision need not be carried quite so high on the side of the face; but, in other respects, should be made in the direction just described. The bone, however, will have to be divided behind, as well as in front of the tumour. In a case under the care of the author, about half of the right side of the lower jaw was implicated by a growth, which proved to be a round celled sarcoma. For its removal, the external incision was confined to a line drawn along the lower border of the inferior maxilla from its angle to the symphysis; the cheek was then dissected up freely, and the bone divided from below, just in front of the angle and also close to the right of the median line. Subsequently the detached piece was readily separated from the inner attachments, and the wound brought together by sutures. Very little disfigurement followed. If the division of the lower lip can be thus avoided the disfigurement will of course be very much

lessened than if cut through. The remaining stages of the operation are comprised in securing all bleeding vessels and in bringing the edges of the wound together. Silver sutures are probably most useful here. They should be introduced at frequent intervals, so that the corresponding portions of the side of the face be accurately adjusted to each other. The extreme vascularity of the tissues generally secures rapid union and a speedy recovery. The inner surface of the cheek should be supported with a fold of wet lint. The dis severed muscles soon adapt themselves to their novel duty, and within twenty-four hours are capable of supporting the tongue sufficiently to enable it to perform its usual offices, without fear of its retraction towards the pharynx. The chief inconvenience as regards the portion of the jaw which is left is, that it is apt to be drawn inwards. But if a thin cap of metal be prepared previous to the operation, so that the upper and lower teeth can be secured by it, it may be applied, as soon as the operation is completed, with great advantage. It steadies the parts, and does not interfere with the administration of food. This latter should be fluid, and may easily be sucked in between the lips, without separating the teeth on the sound side. The jaw should be supported by a handkerchief or bandage passed under the chin, and fixed over the head. Formidable as these operations may occasionally be, patients usually convalesce satisfactorily; nor is the disfigurement subsequent to the removal of a large portion of the lower jaw, or even the whole bone, so great as might be expected. In men the cicatrix can be partially hidden by whisker and beard; and in women a little artificial ornament will readily conceal the greater part. The material deposited in the situation of the original bone assumes a shape much like that of the jaw itself; becomes firm and fibrous, and able to support a plate with artificial teeth.

If the whole of the lower jaw is to be removed, the incision should extend from one side of the face to the other. Starting from over the articulation, the incision, on arriving at the chin, instead of being carried up towards the lip, should be carried onwards to the opposite angle of the jaw, and then upwards to the condyle. This is a formidable operation. If practicable, considerable facility may be obtained by dividing the symphysis immediately after the exposure of the surface of the whole bone. This step will be found to accelerate, and render much less complicated, the separation of the muscles and soft tissues from the inner surface of the bone and tumour, and especially aid in the more rapid disarticulation of each condyle.

The extensive incision necessary for the removal of a large portion of the lower jaw unavoidably passes across and divides the larger branches of the portio dura; the result of which is loss of power over the cheek, and a drawing over of the mouth to the opposite side. This disfigurement at first is generally considerable; but appears usually to improve by time, though it rarely entirely disappears. Mr. Syme succeeded in removing a tumour confined to the ramus of the jaw by a modified incision on the side of the face, commencing over the tumour, and continued down towards the angle, and then forwards, without cutting into the mouth. The ramus, with the condyle, was successfully removed.¹ During operations for removal of tumours connected with the lower jaw, the patient should sit up rather than lie down. The blood thus escapes externally, more readily than into the throat. We should not do justice to British surgery did we omit to mention that Mr. Anthony White, Surgeon to the Westminster Hospital, was the first to remove a portion of the lower jaw. In 1804, it appears, he set the example, and thus established the practicability of the operation.²

The operations requisite on the upper jaw vary according to the nature of the disease affecting it, and the extent to which the walls of the antrum are implicated thereby.

Small tumours growing from and involving the alveolar processes may be usually removed without external incision, as described in the lower jaw. Cysts of the antrum or gums may be attacked with trocar or knife, by first pushing up the lip, or drawing upon the angle of the mouth. But when it becomes necessary to remove a

¹ Syme's *Contributions to Pathology and Surgery*, p. 21. 1848.

² *Medical Gazette*, 1840, vol. ii. p. 620.

portion of the superior maxilla, the direction and extent of the external incisions are very important. When the tumour is small, and it is supposed to be limited to the inner surface of the antrum, or projects from thence into the nostril, an incision through the middle of the upper lip into the corresponding nostril, continued upwards from the attachment of the ala for an inch or more along the side of the nose, will enable the surgeon to dissect off a considerable flap, and uncover a very large portion of the superior maxillary bone.

When it is considered requisite to remove the whole of the superior maxilla with a large tumour, a second incision to that described will be requisite. This second incision must be carried through the cheek, from the inner surface of the angle of the mouth, obliquely to the prominence of the malar bone; or if the tumour be very considerable, and implicates the malar bone, the incision can be run outwards over the zygoma; an ample flap may thus be secured, when the soft parts are dissected upwards from the anterior surface of the bones.

If, when the requisite incision is made, and the bone sufficiently exposed, it should appear that the disease is confined to the inner wall of the antrum, or growing from it into the nostril, the nasal bone should be cut through, and turned partially to one side, without entirely separating it from its periosteal attachments. Thus the nostril will be laid fully open, and the tumour can perhaps be removed without cutting away more bone. If this measure be successful, the nasal bone may be replaced, the flap of skin brought over it, and secured with sutures.

If the disease is found to affect the lower half of the antrum, and the orbital plate is free, then the latter may be left, and the former removed. The incisor teeth of the side affected having been extracted, the alveolus in front should be partially divided with a small fine saw; the surgeon cutting from the nares downwards. The cutting-forceps should complete the division of the bone backwards with that of the hard palate. A line of incision had better first be made along the mucous membrane of the latter, on the side of the median line which is affected by the disease. Then the bone immediately below the margin of the orbit, and from the nostril to the outer edge of the malar bone, must be cut through with saw and bone forceps, and the attachments of the soft palate separated with the scalpel. The portion of bone to be removed should then be seized with strong forceps, when, by means of a few additional cuts with the knife, the surgeon will be able to dislodge the lower portion of the maxillary bone, with the tumour attached.

If it be requisite to remove the whole of the superior maxilla, the external incision which extends in the direction of the zygoma must be continued backwards sufficiently to allow of the free exposure of the zygomatic process of the malar bone. When the flap of the cheek has been freely dissected upwards to the margin of the orbit, the floor of the orbit must be cleared carefully of the attachment of the inferior oblique muscle, &c. The zygomatic process of the malar must be notched with the saw; the alveolar ridge similarly treated; and then the bone cutting forceps employed. One blade of the instrument should be introduced into the nostril, the other at the inner and inferior portion of the orbit; great care being taken that the eyeball is not injured. The blades of the forceps should cut through the nostril and floor of the orbit to the speno-maxillary fissure; the malar bone should be cut through its middle, right back to the anterior extremity of the same fissure; and the hard palate, on the same side of the septum nasi, should be cut back to the posterior border. Thus the tumour and bone will now only be held by a few attachments of soft tissue, which the knife easily separates. The bone can then be removed with slight forcible manipulation, or by twisting it in the grip of a pair of strong forceps.

The hæmorrhage in such an operation is usually greater from the flap than from the rest of the exposed surface; but generally subsides in a short time, so that many ligatures are rarely requisite. The hollow left by the removal of the bone should be partially filled with wet lint, and the edges of the flap secured as already described. In such operations the patient should sit in the upright position, that he may readily get rid of the blood from his mouth.

Tumours of the upper jaw vary so materially in size, in prominence, and direction, in their point of origin, and in many other circumstances, that, in the direction and extent of the external incisions, much latitude must be given, and much left to the judgment of the surgeon. Langenbeck has described several operations for the removal of tumours of the face. The peculiarity of these operations is, that he has endeavoured to separate the periosteum from the bone (when necessary to remove the latter), and to preserve the former in connection with the soft parts. He believes that he has obtained recovery without deformity by so doing; while, if he had removed the periosteum, deformity would have resulted.

He has also adopted an operation, which he terms osteoplastic resection of the upper jaw. This operation is performed when the origin and growth of the tumour is behind the superior maxillary bone, but cannot be reached without displacing that bone.¹ Instead of removing the superior maxilla entirely, the requisite external incisions are made down to the bone at once, the bone sawn through in the same incisions, and the portion thus partially detached forcibly turned inwards, without otherwise dividing it from its connections with the nasal and frontal bone. The tumour is then removed from behind the bone, and the latter replaced in its original position. No incision is made at the place where this fracture or bending must necessarily occur.

Langenbeck's observations, and the cases he records, are too lengthy for us to introduce here; we must therefore refer the reader to the original.²

DISEASES OF THE PHARYNX.

Congenital defects of the pharynx are rare, and when they occur are associated with such other conditions of the fœtus as to render them incompatible with life; so that no practical importance attaches to their consideration.

Inflammation of the pharynx is generally a continuation of a similar condition of the fauces and soft palate, but is, though very rarely, seen to exist alone. When complicated with inflammation of the fauces and glottis, the inflammation appears to partake of the erysipelatous and diffuse character, and often terminates in purulent infiltration of the cellular tissue.

The general conditions indicative of this form of inflammation are described in the essay on DISEASES OF THE LARYNX. Difficulty in swallowing; laboured respiration; swelling of the throat, often observed externally; swollen and rounded uvula and margins of soft palate, hiding from view all behind them, are the prominent symptoms. The tongue soon becomes brown and dry, the lips covered with sordes. The patient dies suddenly in a spasmodic effort to respire, or gradually sinks. Usually death takes place at an early period, and often sooner than may be anticipated. A patient, well to day, is attacked in the evening with sore throat and difficulty in swallowing; these symptoms are soon followed by great obstruction to respiration, entire loss of sleep, rapid pulse, and hot skin, in the course of three days, or four at latest, with all his faculties clear, and while able to direct by motion or writing those around him, the patient's head falls back, and he is dead.

If the parts be examined after death, there will be found a lema of the sub-mucous areolar tissue, around and in the substance of the constrictors, and travelling down around the œsophagus as low as the cardiac extremity. Often the areolar tissue is the seat of purulent infiltration. The treatment of such cases is most frequently hopeless. As long as the patient can swallow, as long as the mischief stops short of purulent infiltration, there is hope of recovery, and encouragement to persevere with the administration of stimulants and nutritious fluid food, if they can be swallowed; or with enemata of wine, quinine, and beef-tea. Laryngotomy should be performed when danger of suffocation becomes evident, or if the patient is suddenly attacked by spasm of the larynx threatening immediate death. Even if the benefit from

¹ As in Mr. Hewett's case, referred to on p. 531.

² *Deutsche Klinik*, 1859, No. 48, p. 470; and 1861, No. 29, p. 281.

laryngotomy be not permanent, it affords much immediate relief to the distress of the symptoms, and certainly prolongs life in most cases.

W. S., aged 45, was admitted on the 29th of September, 1845, into St. George's Hospital, with difficulty of breathing and swallowing, and all the symptoms of diffuse cellular inflammation, extending down the pharynx and oesophagus. On the 2nd October, at five A.M., he was attacked with a paroxysm of dyspnoea, and became quite black in the face and insensible. Laryngotomy was at once performed; and after artificial respiration had been kept up some time, consciousness returned; but it was found that the patient was utterly unable to swallow anything, and he died the following day. The effusion of lymph extended from the cellular tissue round the glottis downwards around the oesophagus, in the anterior as well as the posterior mediastinum, as low as the diaphragm.¹

It will be evident to the reader with the above case before him, that when the mischief extends beyond and below the pharynx, and the infiltration is of a purulent character, no possible advantage can be derived from any form of treatment. The patient dies, either in a paroxysm of dyspnoea, or poisoned by the pus locked up in the cellular tissue of the thorax.

Abscess of the pharynx is an occasional occurrence; is generally a formidable evil; and is often as a cause or result connected with some disease of the cervical vertebrae. Much care must be taken to arrive at a correct diagnosis of such a case; for it may readily be mistaken for a polypoid or other solid growth of the walls or cavity of the pharynx.

The following case well illustrates the importance of this precaution:—An abscess, the size of a pigeon's egg, was situated between the bodies of the upper cervical vertebrae and the back of the pharynx, but from being flattened in front did not cause any material projection of the posterior wall of the pharynx. In connection with the abscess, a second small cyst was prolonged forwards, so as to form a nipple-like swelling in the pharynx; and this compressed and completely closed the orifice of the glottis. The aperture of communication between this process and the body of the abscess admitted the point of the little finger; and the whole swelling was freely movable and perfectly translucent at its extremities and sides. This abscess occurred in an infant seven months old, who had suffered from dyspnoea for three weeks. The difficulty of breathing became very urgent three days before death; was constant, though less urgent at intervals; but the slightest exposure to cold, any motion or excitement, brought on a recurrence of threatened suffocation, attended by a peculiar croupy inspiratory sound. There was no attendant difficulty of swallowing, and no other disease was found after death.²

Abscess may arise from an injury to the pharyngeal membrane, caused by the passage or the impaction of a foreign body. In the Museum of St. George's Hospital is a preparation which shows an irregular ulcer, communicating with an abscess, on the posterior wall of the pharynx, which was removed from the body of a young woman who died from its effects, and who had, some six weeks previous to her death, swallowed some pins, one of which was supposed to have lodged in the pharynx, and produced the mischief which so speedily terminated in death.

Ulceration of the mucous membrane of the pharynx is usually the consequence of syphilis; more rarely it is the result of scrofulous influence. In children, the latter condition is sometimes observed to produce considerable destruction of the soft tissues, and its progress is very difficult to control. The symptoms generally are, offensive breath; offensive purulent secretion from the nostrils, and excoriated nasal apertures; constant cough; and the external characteristics of a strumous diathesis. The ulceration is readily seen when the mouth is opened; is not deep, but irregular, and the edges of the ulcer usually well defined; with crusts of dried secretion, often highly offensive, sticking in patches to its surface. There is not much pain complained of; perhaps some, less or more, is experienced when food is taken.

This characteristic form of ulceration is extremely obstinate in duration, and often extends to the tissues of the soft and hard palate, as well as to the nares. In the case of a little girl in St. George's Hospital, the mischief spread most unrelentingly from the pharynx to the nose and mouth, and from the mucous surface to the deeper tissues; until the nose fell in, and the greater portion of the palate, soft and hard, was destroyed, leaving the child a dreadfully disfigured object.

¹ *Post-mortem and Case Book*, 1845, No. 234.

² *Transactions of Path. Society*, vol. i. p. 61.

This strumous form of ulceration is certainly found to exist in children more frequently than in adults. The treatment is to be directed chiefly to constitutional measures, though local applications may also prove beneficial. It should consist of the various tonics which are beneficial in the management of scrofulous cases generally, aided by good living, great attention to cleanliness and pure air, and, if within the means of the patient, a sea-side residence; the Isle of Thanet is especially to be recommended.

Syphilitic ulceration of the pharynx is very commonly observed, especially in the lower classes of the metropolis. It is constantly seen to attack the posterior wall of the pharynx; but is usually accompanied by ulceration of the velum or tonsils, or some other secondary evidence of the prevailing poison.

Its character may be suspected by the age of the patient, the period of its duration, and other symptoms which may be present; *i.e.* rupial sores in the skin; nodes of the skull or other bones; pains in the limbs or joints; general reduction of health and flesh; and last, not least, the confession (not always to be obtained) of a former primary sore, with perhaps a mark of its recent habitation.

Such an ulceration will usually yield rapidly and satisfactorily to treatment. It granulates, contracts, and cicatrises under the influence of iodide of iron, or iodide of potassium alone; and if thus treated in its earlier conditions, leaves behind but little to mark locally its former existence.

It happens, however, in some instances—whether from neglect, or from misapplied treatment, or from a state of deteriorated constitution—that there arises a greater virulence in this ulcerative action; and that the ulceration spreads not only to the sides and posterior wall of the pharynx, but also implicates the velum and arches of the palate, leaving a very extensive surface entirely denuded of mucous membrane. Under such circumstances, the patient will be found in a deplorable state; he has great difficulty in swallowing, and he becomes greatly reduced from inability to take sufficient nourishment. When, under judicious treatment, cicatrisation commences, it will generally be found that as the ulcerated surface contracts, the soft palate becomes displaced, and adherent by its margins to some portion, or occasionally to the entire surrounding surface of the pharyngeal wall. As a result, the soft palate has been occasionally seen adherent to and continuous with the wall of the pharynx, so that all communication between the latter and the nares was entirely cut off. An operation should be attempted partly to relieve this evil; there is usually much difficulty in again preventing adhesions of the parts during cicatrisation; but as the sense of smell is very much impaired as long as the communication between the two cavities is closed, it is most desirable to establish a permanent aperture in the soft palate under such circumstances; and in all probability the perseverance of the surgeon in his efforts to effect it will ultimately prove successful.

Dilatation of the pharynx may occur in two forms: it may be dilated throughout, or only partially. The latter condition is met with occasionally: the former very rarely. The symptoms noticed in cases in which a pouch has been found after death, are difficulty in swallowing much food, and vomiting of food which has been felt to stick in the throat. In one case, the patient (who died at the age of ninety) was accustomed to press on the pouch and force the food into the œsophagus.

In the Museum of St. George's Hospital is a specimen showing dilatation of the lower part of the pharynx, at a point corresponding to the lower border of the inferior constrictor muscle, and forming a pouch equal in size to that of an egg. The pouch projects downwards behind the upper part of the œsophagus: it is apparently composed of a portion of the mucous membrane and sub-mucous tissue protruding through the muscular coats of the pharynx, and does not show any muscular fibres entering into its formation. The upper portion of the pharynx is enlarged, and the pharyngeal muscles are hypertrophied. There is no stricture of the œsophagus.

The preparation was removed from the body of a man aged sixty-three, who for several years had suffered from difficulty in swallowing. After the conclusion of a meal he was in the habit of returning small portions of food. For two or three years previous to his death

he was subject to attacks of inflammation of his larynx, from which he recovered under treatment. His death was the result of inflammation of the lungs. The dysphagia was always supposed to be owing to stricture of the œsophagus.

Tumours attached to the pharynx are not very common. When they occur, they are generally apt to be somewhat pendulous, and are often attached to a portion of the walls by a narrow neck. They have been found to consist of fat, fibrous or fibro-cellular tissue. But the character of the growth is perhaps of less importance as regards the immediate treatment, than the shape, the size, the position, and the attachment of the mass.

The record, with a coloured illustration, of a fatty tumour of the pharynx, is to be found in the 'Transactions of the Pathological Society,' vol. v. p. 123, by Mr. Holt. This specimen was removed from the body of a man eighty years of age. Twelve years previously, his attention had been first drawn to his throat, from an occasional sensation of choking. About four years previous to his death, during an attack of vomiting, a large mass was protruded into his mouth; and, to prevent immediate suffocation, he was compelled to return it as quickly as possible. He was at all times better able to swallow fluids than solids. He died suddenly, while in the act of smoking.

The tumour was found to be a large, pendulous, fatty mass, filling the pharynx, and extending downwards to the œsophagus for nine inches. It was attached by fibrous tissue, covered by mucous membrane, to the left side of the epiglottis, and also to the upper part and side of the pharynx. The tumour had by its weight so dragged upon the epiglottis, that the perfect closure of the laryngeal aperture was not practicable. The mass, except at its attachments, was hanging loose in the pharynx and œsophagus. It consisted of adipose tissue.

FIG. 131.—Pouch of the Pharynx. (From a preparation in the Museum of St. George's Hospital. Ser. ix. No. 14.)

In the Museum of the College of Surgeons are two specimens of tumours of the pharynx, successively removed during life. One¹ is a large, soft, lobulated mass, apparently fatty or gelatinous, like a nasal polypus. It was attached by a narrow pedicle behind the tonsil. A second² is apparently a firm, fibrous mass, and was attached by a narrow pedicle to the wall of the pharynx.

Other cases have been observed in which tumours, either of fatty or fibrous structure, have encroached on the cavity of the pharynx without becoming pendulous; they have been seen to grow and insinuate themselves under the mucous membrane; and as they increased in size, so they interfered with the aperture of the glottis, and interrupted the passage of food to the stomach.

The treatment of tumours located in and attached to the walls of the pharynx is often attended by some difficulty, but their removal

should be attempted, and that at as early a stage as possible.

The only hope of benefit must be from treatment restricted to the pendulous form of tumour. The attempt to remove a tumour attached throughout to the walls of the pharynx would be a highly hazardous proceeding, and most probably unsuccessful in its results, if not fatal during its progress. When the tumour is pendulous, no time should be lost before the endeavour be made to remove it. If not large, and attached to the upper part or side of the pharynx, it may be seized with a volsellum, and the pedicle cut through with a knife. If the mass appears very vascular, or large vessels are detected running through the pedicle, a double ligature may be first passed through the base, and when securely tied the mass may be with safety cut off beyond it. A ligature through the pedicle is far preferable to one round it; for when the mass beyond is removed by the knife, the ligature is apt to slip off, and possibly some hæmorrhage might ensue.

¹ No. 1000.

² No. 1091.

The chief, and probably the only risk the surgeon has to fear in an attempt to remove a polypoid mass from the pharynx is that of suffocation, produced either by the mass itself filling up the fauces and pressing down the epiglottis, or by spasm of the glottis, the result of irritation from the tumour coming in contact with the surface of the laryngeal mucous membrane. This risk, however, may be effectually guarded against by the use of the tracheal 'tampon.' This apparatus should be employed in any operation in which there is danger of suffocation from pressure of the tumour on the orifice of the larynx, or of the chance of much blood passing down the trachea and thus embarrassing respiration. Under these circumstances tracheotomy has first to be performed, and then the tampon fixed at the opening around the tracheal tube. By the adoption of these measures, the entrance of blood into the bronchi is effectually prevented, while respiration is in no degree interfered with. If the character of the tumour recorded in the 'Transactions of the Pathological Society' by Mr. Holt be considered—its attachments, its size, and the extreme feasibility of its removal, either in great part or in its entirety, that it could not have been drawn into the mouth without the aperture of the glottis being stopped up, but that otherwise the mass might easily have been drawn forwards, and the greater portion removed, the important aid of this instrument will be at once appreciated. It might be necessary or desirable to retain the tube for a few days, or until the wound occasioned by the removal of the tumour had commenced to granulate and contract.

DISEASES OF THE ŒSOPHAGUS.

Congenital malformation of the œsophagus is rare. It usually proves fatal within a few days of birth.

Dilatation of the œsophagus, and *pouches* connected with that tube, are of occasional occurrence. Cases of the former have been put on record by Rokitsky¹ and by Dr. Barker.²

Contraction of the œsophagus is a very common evil. It is usually an insurmountable difficulty to the surgeon, and in the majority of cases rapidly reduces and destroys its victim.

Contraction, or 'stricture' of the œsophagus, may be the result of several distinct conditions. Folds of the mucous membrane; cicatrices after injury; pressure occasioned by aneurism or tumour; thickening and contraction of the walls; or, lastly, and most frequently, cancerous affections of the tube, are the chief causes of stricture of the œsophagus.

In the Museum of the College of Surgeons is a specimen (No. 1079) which shows stricture of the œsophagus from a fold of mucous membrane. Just below the cricoid cartilage, the œsophagus gradually contracts to half its diameter, and then dilates. The mucous membrane at the contracted part forms transverse, sharp-edged, and projecting folds, which pass round the chief part of the circumference of the tube. The surrounding tissues are also condensed, as if the result of cicatrix. There is no history to the specimen. Another preparation (No. 1080) shows a very similar condition in the œsophagus of a child, probably the result of some acrid substance having been swallowed. A preparation removed from the body of a boy ten years of age shows a contracted state of the œsophagus, subsequent to the action of sulphuric acid swallowed during life. With respect to the changes subsequent to the passage of an acrid poison over the mucous surface of the œsophagus, Rokitsky remarks that when 'the mucous membrane has been destroyed by the energetic action of the poison, it is replaced by serous and sero-fibrous tissue, which gives rise to peculiar valvular strictures of the œsophagus, somewhat analogous to those consequent on dysentery.'³

In the Museum of St. George's Hospital is a preparation of a portion of an œsophagus, in which may be seen a constriction about three inches from its upper extremity—the result of a piece of bone becoming impacted for a time in the passage, and having set up inflammation around the part. This mischief extended to the præ-vertebral areolar tissue of the cervical region, followed by ulceration of the intervertebral cartilage of the third and fourth cervical vertebrae. The ulceration went on to perforation of the spinal canal, and produced

¹ *Path. Anat.* vol. ii. p. 9. ² *Path. Soc. Trans.* x. 140.

³ *Op. c.* vol. ii. p. 10.

inflammation of the membranes and softening of the spinal cord. The piece of bone, of considerable size, had stuck in the throat for a time, but was subsequently removed. Large quantities of pus were afterwards spat up.¹

Simple stricture of the oesophagus, from thickening and contraction of its walls, is occasionally met with, and apparently without satisfactory explanation. Mr. Liston exhibited at the Pathological Society a specimen possessing some interesting features. The stricture existed at the upper part of the tube, was about an inch in length, and only capable of allowing the passage of a goose-quill. The contraction had existed for a number of years; there was considerable hypertrophy of the constrictors of the pharynx, especially of the superior one. The upper horns of the thyroid cartilage were so approximated as to leave but a space of $\frac{1}{8}$ th of an inch, being a diminution of about an inch in the breadth of the natural interval between them. The patient had been under the care of Cruikshank and John Hunter, and lived to between seventy and eighty.

It is unnecessary to multiply instances of these forms of contraction; there are, however, certain circumstances in connection with their progress, which will form the subject of consideration when their diagnosis and treatment are discussed.

Complete obstruction to the passage of food from the pressure of a tumour on the oesophagus is very rare. Occasionally some degree of difficulty in swallowing is experienced, from the presence of a tumour of a cancerous nature; or from the thyroid, when very large, or when it wraps round the trachea; or from an aneurism or any other kind of swelling in the neck.

Evidence of supposed pressure from a tumour must, however, be carefully weighed before a decision be arrived at respecting its influence in this respect. Dr. Wilks² has very properly drawn attention to the circumstance that obstruction has been attributed to an exostosis of the vertebrae when actual disease of the oesophagus and stricture existed above the seat of the exostosis.

The most frequent causes of obstruction to the passage of food, attended by rapid deterioration, and followed by early death, are cancerous affections of the oesophagus. They occur in various forms. The epithelial variety of ulceration with contraction is most common, but medullary, villous, or colloid cancer occur somewhat in proportion to the order in which we have placed them.

Cancerous ulceration or stricture of the oesophagus is a disease of age. We are not aware of its occurrence in youth or early life. Rokitsansky states that 'cancer of the oesophagus generally occurs in an isolated form, i.e. without the co-existence of the disease in other organs.'³ Such is no doubt often the case, but the rule is made too general to be correct; the reader may satisfy himself that we differ with the great pathologist on reasonable grounds by reference to the 'Transactions of the Pathological Society.'

The usual symptoms of stricture are, first, a slight difficulty in the passage of solid food to the stomach. The difficulty gradually increases; sooner or later the patient is compelled to restrict himself entirely to food of a fluid form. By degrees he finds that this he can take only in gradually reduced quantities, until at last he sips but a few drops at a time; or even this small quantity may be rejected, shortly after an attempt made to swallow it.

A patient with organic stricture of the oesophagus rapidly emaciates, unless food can be introduced into the stomach by aid of a tube; the circulation becomes feeble, he complains of a sensation of cold on temperate days, and he becomes very susceptible to all changes of the atmosphere.

If there be ulceration in the upper part of the oesophagus, or the pharynx be also implicated, there is generally a disagreeable smell in the patient's breath, easily detected by a visitor on entering the room. The patient is often subject to expectoration, and the secretion spat up is semi-purulent, and occasionally very offensive. He complains of intense hunger in the earlier period of the disease, and when solid food can no longer be taken; but gradually he succumbs to the privation, and latterly is often indifferent respecting it.

When once the contraction of the stricture restricts the patient to fluid nourishment alone, the quantity taken is by no means sufficient to sustain life; so that should not some means of relief be adopted the medical attendant may predict the

¹ *Post-mortem Book*, 1862, fol. 80.

² *Path. Soc. Trans.* vol. xii. p. 101.

³ *Pathological Anatomy*, vol. ii. p. 12.

approaching end as not far distant, when perhaps the patient or his surrounding friends may be little prepared for such an announcement.

Occasional complications occur in the progress of stricture of the œsophagus to which our attention is requisite; they render the disease more distressing to the patient, but generally hasten the termination of his sufferings. The epithelial variety of ulceration is apt to spread superficially, without destroying the tissues deeply; and though a large surface may be implicated, the patient so affected will survive longer than one affected by the medullary form of cancer. With the latter form of disease the surrounding tissues become implicated at an early period, and thus the passage may become much constricted soon after the stricture is suspected. Ulceration of the tube above or about the diseased mass will generally take place, and cavities in the cellular tissue around will be constantly found communicating with the ulcerated points of the œsophagus. Occasionally the destruction makes its way outwards, until several openings are formed externally about the neck, and allow the escape, not only of matter, but also of the fluids taken as nourishment. Or the ulcerative action may run in a different direction, burrow about the muscles of the neck, or effect a fistulous communication with the trachea. The latter condition is made evident by fluids, taken through the mouth, being coughed up through the glottis.

In other instances, almost instantaneous death will occur from sudden and violent hemorrhage, dependent on the ulceration of a large artery.¹

The symptoms of stricture of the œsophagus are so marked, that it might at first, sight appear almost impossible to be deceived regarding its occurrence. But an hysterical spasmodic condition of the pharynx or œsophagus is occasionally met with and might be mistaken for organic mischief, without some precaution and judgment brought to bear on the case. It is therefore prudent to weigh carefully the symptoms of all cases of supposed stricture of the œsophagus, in order to be able to discriminate between actual stricture, and that of nervous origin. The latter disorder is not very commonly met with; but it will be found, as a rule, to occur in women. In two instances familiar to us, the symptoms were evidently entirely due to the state of health, and yielded effectually to constitutional treatment. The symptom which commonly distinguishes an hysterical or spasmodic difficulty in swallowing from a real stricture is the easy manner in which a patient can swallow fluids, or even solids, when allowed to take them apparently unobserved. There is little, if any, emaciation; nor is there the early indication of loss of strength, nor the constant desire for food if it could only be swallowed.

Although the existence of a stricture itself may be generally ascertained without difficulty, the cause of the obstruction is not always so satisfactorily detected. The chest should always be carefully examined, with a view to satisfy oneself that neither aneurism nor any other mass was pressing on trachea or œsophagus. This having been done with the conviction that no external pressure was the cause of the impediment to the passage of food, a very careful and very gentle examination may be made with a gum catheter or small œsophageal tube. If this can be passed with but the very slightest pressure, it may reveal the fact that the obstruction is due to some simple cause of contraction, and is not one of a cancerous nature.

The author was consulted by a lady, about thirty-eight years of age, who had for some weeks experienced an increasing difficulty in swallowing solid food, and could take little else than fluid nourishment, and this only with care and in small quantity at a time. There was no history of any injury from having swallowed any acrid or caustic fluid, bone, or other substance to cause abrasion, or give rise to ulceration. There was no pus or offensive odour in the fluid rejected after attempts to swallow nourishment. A thin œsophageal tube was introduced, and very gently passed till it reached an obstruction, some eight or ten inches down the œsophagus. After

¹ A case is recorded in the *Transactions of the Pathological Society* (vol. ix. p. 194) of death by hæmorrhage from ulceration extending from the œsophagus to the right subclavian artery. And a second instance is found at page 202 of the same volume, in which death was the result of perforation of the superior intercostal, by extension of ulceration from the cancerous stricture. The vertebral artery has been known to be perforated under similar conditions.

waiting a short time, the tube was passed through the obstruction and readily reached the stomach. The patient soon learned to use the instrument herself, and in a short time was able to pass one the diameter of a No. 18 catheter. She has continued to use this tube daily three or four times ever since, and to feed herself through it. Her health has continued good. In order to economise time and save trouble, a long flexible rubber tube was attached by one end to the œsophageal tube, and by the other to a vessel capable of holding about a pint and half of fluid. This vessel was each time filled with milk, mixed with eggs, flour, strong soup, or wine, and was then fixed about a foot above the patient's head. The tube having been introduced into the stomach, a tap attached to the vessel is turned, and the contents of the latter flow into the stomach. A similar apparatus was supplied to a patient in St. George's Hospital, who was admitted under the care of the author for difficulty in swallowing, the result apparently of some obstruction of the œsophagus dependent on simple contraction. Similar treatment may be followed in all cases in which the obstruction is due to cicatrix or other non-malignant causes.

If, however, there is much difficulty in swallowing, much emaciation, offensive fluid, mixed with pus, or occasionally blood, rejected with the food attempted to be swallowed, the conclusion to be arrived at will certainly be that the stricture is of a cancerous nature, and in most cases such a conclusion will not prove wrong. The use of a tube of any kind must in such a case be only attempted with the greatest care and gentleness; rather as a means to confirm one's opinion than with any prospect of benefit to the patient. If the slightest obstruction is met with, the tube had better be withdrawn at once. Any pressure may readily cause mischief, by causing the tube to pass into the mediastinum or pleura, or even pericardium.

When a pouch of the pharynx or œsophagus exists, it may be suspected, if, after partaking of food, the patient feels any fulness in the neck, or if, after a time, a portion of the meal is returned. As the pouch is capable of holding a certain quantity, there is not so much difficulty in disposing of a portion of solid food as in stricture; for a part may pass into the œsophagus, and the rest into the pouch. A patient suffering from a pouchy condition of the tube does not emaciate as rapidly as one affected by stricture; several instances on record are stated to have lived to a good old age.

The treatment of hysterical contractions of the œsophagus should be constitutional rather than local; though the introduction of the tube in the first instance may occasionally be desirable, to confirm the opinion that no permanent obstacle exists to prevent the patient taking food. Such cases usually yield to proper treatment without much difficulty, though occasionally in young women some little patience and skill are required to remedy the disordered state which gives rise to this nervous affection. Seldom, however, do we find patients of this class deprive themselves of food to such an extent as to cause emaciation.

When the stricture is proved to be permanent, whether the result of cancerous or cicatricial contraction, and death by starvation is the probable sequence, the operation of gastrostomy is one alternative by which the surgeon may attempt to prolong life, and so far mitigate the sufferings of the patient. This operation has been frequently had recourse to, with results which in a few cases may be considered somewhat satisfactory.

More recently, however, the operation of opening the œsophagus in the lower part of the neck and below the seat of stricture, to enable food to be introduced through the opening into the stomach, has been advocated, and adopted in a few instances. The subject is one of considerable practical interest. At present, however, our experience is not sufficient to justify any decided rule to be laid down as to which operation should be generally selected as least dangerous or most efficacious. In the majority of cases we have to deal with a disease which sooner or later will prove fatal; it is, therefore, practically a choice of the lesser evil. In the large majority of cases the seat of stricture may to a certain extent be pretty accurately defined; not so, however, the extent of the disease beyond its commencement. If the stricture, as often occurs, be situated high up, œsophagotomy may be fairly adopted

with good prospect of reaching a healthy portion of œsophagus below the seat of contraction ; but when the obstruction is known or suspected to be lower down, there can be but the alternative of gastrostomy.

Mr. Reeves, in an interesting and able communication to the Clinical Society,¹ last year drew attention to this subject. After narrating the particulars of two cases of malignant stricture of the œsophagus, in which gastrostomy was performed, he pointed out that, having thus operated in deference to the opinion of his colleagues, he should proceed to open the œsophagus in any suitable case of stricture of that organ in preference to opening the stomach. He observed that recent investigation proved that malignant obstruction was most commonly situated in the upper part of the tube, and a larger number of observations were needed to enable us to arrive at any correct conclusions, still there was sufficient justification for the rules he wished to lay down : viz. '1. That because of the great mortality of gastrostomy, and also because of the more frequent occurrence of malignant stricture in the upper portion of the tube, œsophagostomy is by far the preferable operation. 2. That even in cases in which the stricture is as low down as the manubrium sterni (its depth rarely being very great), œsophagostomy is indicated as a preliminary or exploratory operation, and if it be found that the little finger or sound cannot be got through the stricture, gastrostomy may be performed. 3. That if it result that the opening in the œsophagus have been made below the stricture, as in most cases would be desired, the operation can be completed by stitching the mucous membrane to the wound-edges, and the stricture may, if thought proper, be dilated through the opening, either at the time of the operation or subsequently. 4. That if the diseased œsophagus be reached, and no opening into it can be made through healthy walls, then it may be carefully perforated, either by the finger or the thermo-cautery. 5. Œsophagotomy has been many times done, and œsophagostomy several times, and never have these operations caused any grave local or general symptoms, or as operations led to the death of the patient, whereas gastrostomy has proved most fatal.' 6. The operation should be done on the left side of the neck, and a sound should, if possible, be passed - that of Vacca Berlinghiéri being the best. The skin incision should be rather nearer the middle line than that for ligature of the common carotid, and should extend from half an inch above the episternal notch to the level of the upper border of the thyroid cartilage. The surgeon should stand on the left of the patient, looking obliquely down and across the body. A tube with a funnel-shaped end should be passed and tied in place, and nourishment administered as soon as tendency to vomit has passed off. It is necessary to make the opening in the walls of the œsophagus with a sharpish stab, to prevent the loose mucous membrane being pushed before the knife. The edges of the wound may be stitched up and care taken that no food gets into it. 7. The operation should be undertaken 'before the patient's strength is much exhausted, and even before obstruction is complete, because frequently attempts to swallow produce spasmodic suffocative dyspœa. 8. In a severe case of fibrous or syphilitic stricture in the nuchal or upper thoracic portion of the tube, œsophagostomy is indicated, as then the operation might be curative as well as palliative.'

Mr. Reeves is reported² to have operated on a man at sixty, on account of malignant obstruction of the œsophagus. Œsophagostomy was undertaken and successfully completed. It was difficult to recognise the œsophagus. The case is still under treatment.

Mr. Holmes,³ Surgeon to St. George's Hospital, has also reported a case in which he opened the œsophagus in a case of stricture complicated with an enlarged gland or growth in the upper and left side of the neck, and in which the obstruction appeared to be about the upper border of the thyroid cartilage. Mr. Holmes succeeded in opening the œsophagus through healthy tissues and below the seat of stricture. Very little blood was lost in the operation, but the patient, already much reduced and emaciated, gradually sank and died about three days after the operation. Post-mortem examination showed that 'the opening had been made about an inch below

¹ *Lancet*, Nov. 5, 1881, p. 796.

² *Ibid.* July 15, 1882, p. 75.

³ *Medical Times and Gazette*, July 29, 1882, p. 117.

the lower edge of the thyroid body, and the recurrent nerve lay quite close to it, almost in contact with one of the ligatures passed through its lip; but had not been touched or injured in any way. The main tumour occupied the site of the right great cornu of the hyoid bone, which seemed lost in its substance. It was adherent to the thyroid cartilage also. In structure it resembled epithelioma to the naked eye, but there has not yet been any opportunity for microscopical examination. The thyroid body, which was very large, was infiltrated in its deeper portions with a similar whitish deposit, and they had implicated the coats of the Œsophagus, so as to produce considerable constriction. On passing the end of the little finger down, it felt at first as if the food tube was closed; but by steady pressure the finger could be pushed through it. The seat of the stricture was just behind the thyroid cartilage.

Mr. Durham has made a happy suggestion in advocating the use of a flexible bougie, to be retained for some short time in the Œsophagus in some forms of stricture. We have already alluded to a case under our own observation, in which the daily use of a catheter has been followed by great amelioration to health, and great comfort to the patient, and has now been uninterruptedly in use some five years. Such, however, could only have been the result in a simple, not a cancerous, stricture.

As already stated, so it will be found in practice, that when, with severe stricture, maintenance of life depends on a small quantity of fluid food, loss of flesh and general deterioration become so rapid and complete, that a patient will die much sooner than may often be anticipated, with all his faculties clear to the end.

Under such circumstances any operation may even prove too late. The patient may be too much reduced to be able to rally after its performance; or too much exhausted to benefit by the food supplied through the artificial opening; or even it may be that in such a reduced condition sufficiently healthy lymph may not be thrown out so as to secure such adhesion of the opposed surfaces of stomach and external wound as is requisite for the success of the operation. In a case recently under the notice of the author, such a result followed the operation; and when the sutures were removed, the adhesions were not sufficiently organised to maintain the parts in apposition.

GEORGE POLLOCK.

DISEASES OF THE TONGUE.

IN a description of the surgical diseases of the tongue and their treatment such as the present, which must necessarily be short, all minute consideration of the anatomy of the organ will be omitted. It is only needful to remark here that any and all of the structures of which it is made up, whether mucous membrane, muscle, glands, ducts, blood-vessels, lymphatics, or nerves, may be the seat of morbid changes, and are so in different cases. But perhaps the best general order in which to consider the latter will not be primarily an anatomical one, but rather clinical, at all events for the present. The matter in hand, then, will be divided into four sections, as follows. In the first, the *congenital faults* will be considered; in the second, those conditions of the tongue requiring surgical interference which are the *result of inflammatory change*; thirdly, those which are due to the presence of *neoplasms*; lastly, we shall study the *operations* necessary for the removal of the whole or portions of the tongue.

It may be noted here that in infancy and childhood there are comparatively few morbid conditions of the tongue which claim the particular attention of the surgeon; in early adult life, however, their number rises, but it is in middle and advanced age that the most important affections are met with.

CONGENITAL FAULTS.

In the tongue congenital defects are rare as compared with other parts of the body. The first for which we would look almost naturally is *deficiency of development* in the form of absence of the organ; but of this, after long search, I can only find one instance. This was recorded by Jussieu¹ more than 160 years ago. In his interesting memoir, which is well worth reading, he describes the case as one of a girl of fifteen years, who from the time of her birth showed no evidence of the development of a tongue, the floor of the mouth being flat, except for the presence of two small papillæ which moved freely. She appeared to be little, if at all, inconvenienced by this condition, and could speak well. The fact that none of the best known writers on malformation since then, whom I have consulted carefully, from Geoffroy de St.-Hilaire² to von Ammon,³ Förster,⁴ or more recently Ahlfeld,⁵ have been able to add other similar cases to this one, says much for the extreme rarity of the defect.

But the tongue may be otherwise malformed at birth in the direction of deficiency, though still very rarely. Thus it may be cleft vertically, either in the middle, or here and on both sides, forming in the first place a bifid, in the second a three-lobed organ, as figured in Ahlfeld's atlas (*loc. cit.*) In such cases the surgeon might be called upon to freshen the edges of the clefts with the knife, and bring them together with sutures as in hare-lip.

Horizontal clefts are not known, though congenital fleshy tumours under the organ have been mistaken for a second tongue (von Ammon, *loc. cit.*)

Shortness of the *frænum lingule* leads to an extent embarrassing to the tongue, is sometimes met with, though far less frequent and important than is commonly sup-

⁵ *Ibid.* 1880.

posed. This 'tongue-tie' is, so to speak, the dread of young mothers, who fancy that if it exist their child will later on be unable to talk. But instances where it has interfered with speech must be exceedingly rare, if they ever occur, for we know that even complete absence of the organ from birth, as in Jussien's case, is compatible with excellent powers in this respect. And even where the whole tongue has been lost later by disease, the same has been noticed and recorded by Roland¹ and Louis,² quoting Scotchmore's (1743), Bonami's (1763), and Aurrain's (1766) cases. All these records will be read with much interest, especially that by Roland, though for lack of space they can only be briefly alluded to here.

But even if this condition exist to some extent, it is questionable whether in most instances without division the movements of the tongue do not sufficiently stretch the *frænum* before very long. In some few cases, however, it does appear not only shorter than usual, but tougher and less inclined to stretch, and in this state to interfere with sucking by preventing the proper application of the tongue against the palate. Then, and only then, does it call for surgical interference. This will consist in division of the band, either by knife or by scissors. If the first of these be used, the band should be transfixed and cut outwards with a curved blade. But whichever of these instruments is used, a very limited incision in the *frænum* should be made as close to the jaw as possible, in order to avoid both the canine veins and arteries, severe and even fatal hæmorrhage having resulted in some cases from wound of these vessels in the infant, favoured by the efforts of sucking. To another danger from this operation attention has been drawn by Petit,³ and illustrated by three cases from his own practice. If the *frænum* and subjacent muscle fibres be too freely divided, energetic sucking on the part of a hungry child may tear the wound of these very lax tissues further and further open, until the tongue, having lost all its anterior support, turns over into the pharynx, and is firmly embraced by the muscles of deglutition, which force it down upon the epiglottis, and the latter upon the larynx, until suffocation is produced. The mechanism of this displacement is so important, as bearing upon other operations in later life, that a brief notice of these cases, as described by Petit, may be useful here.

The *first* was that of a child whose *frænum* had been divided shortly after birth, and who died five hours later of suffocation. Struck with the peculiar train of symptoms, he carefully examined the mouth by dividing the cheeks as far as the masseter muscles. He then found that the tongue was turned over, so that it had become engaged behind the soft palate, its dorsum resting against the posterior wall of the pharynx, and pressing the epiglottis firmly down upon the larynx at the same time.

The *second* case was precisely similar, suffocation setting in shortly after division of the *frænum* two hours after birth. Here Petit found the tongue in the same position as in Case 1, but was able to replace it with his fingers. Five minutes later the same symptoms recurred, and the tongue was found to have retroverted as before. Eventually, after repeated attacks of the same kind had been watched, he succeeded in keeping the organ permanently in its proper position with a compress. During the following night a careless nurse neglected to replace this compress after feeding the child; the same respiratory difficulty set in, and before Petit could be called in the patient had died suffocated. The tongue was found in this case to lie as in the first.

His *third* experience was precisely similar, but being this time on his guard, the tongue was regularly replaced and effectually retained in position for several days, until all tendency to retroversion was gone, the child recovering completely.

Another effect of deficiency of development involving danger has also been noticed here—namely, the very opposite condition to 'tongue-tie.' The *frænum* has been either so very long and lax or so completely absent that the tongue has been able to turn over into the pharynx precisely as described above after operation, and thus to cause suffoca-

¹ *Aglossomatie*, 1630.

² *Mém. d. l'Acad. Roy. de Chir.* tome xiv. p. 304.

³ *Hist. de l'Acad. Roy. de Science*, 1742; p. 247 of *Mémoires*.

tion. One such case is minutely described by Petit (*loc. cit.*), in which the child had to be closely watched for three weeks, and its tongue repeatedly replaced before it could be left to itself, and had ceased to produce these attacks of suffocation. Two similar cases are recorded by Fairbairn.¹ One, combined with smallness of the lower jaw, was fatal from suffocation; the other, under due care of the mouth, recovered, and was five years old at the date of the report.

Again, the tongue may be present as far as its muscular elements are concerned, but have failed to rise from the floor of the mouth in the usual course of development (see von Ammon, *loc. cit.*) In this condition it gives the impression of being tied down all round the border, and that, if freed here, it would rise to its normal position. Such a view is, however, erroneous. We are probably dealing here with an arrest of development, at a stage in which the tongue does not project upwards into the mouth, and not with any fault in the mucous membrane on the floor of the latter. To divide this, then, would not enable the tongue to rise any more than before, unless development set in once more. Such an error might be serious, as such a free dissection round the floor of the mouth would be a grave operation.

Adhesions have, however, been found at birth around the borders of the tongue, as the result probably of intrauterine inflammation, and have been relieved by simple division of the bands, as in the cases quoted by Clarke² from Sernin and Maurin. Such a condition is, however, as rare as the last, with which it should not be confounded, for here operation is as urgently called for as it is unjustifiable in the case of the congenital arrest of development. A careful examination of the organ will leave little open for a mistake of the kind.

Excess of development is rarely met with in the tongue, as affecting the whole organ, unless we regard the condition known as macroglossia as such (see below). But cases are spoken of by Fournier,³ in which the latter was much longer and extensible than usual, even to the extent of touching the chest with its tip, the head being held erect and the neck being of the usual length.

On the other hand, one or other of the tissues of which the organ is made up may be overdeveloped as a whole or in part, and thus produce enlargement, partial or general. Thus the veins of the tongue have been found engorged at birth as a consequence of a twist in the umbilical cord during intrauterine life, and this condition has taken some days to subside, so long had it existed and so dilated the vessels. Again nævoid dilatations of the veins of the tongue are occasionally met with at birth, as well as hypertrophy of the lymphatic structures, giving rise to the condition known as 'macroglossia.' But, besides these, a variety of tumours may be formed here, in utero, as the result of hypertrophy of part of one of the lingual structures. Thus we find fibromata, lipomata, papillomata, racemose adenomata, as well as dilatation of glands forming ranulae, and even sebaceous cysts. The nature and treatment of all these will be discussed more at length further on in the section on 'Tumours of the Tongue,' whether congenital or acquired.

MACROGLOSSIA.

As holding an intermediate position between the congenital and inflammatory conditions, we turn now to that disease known, since the days of Galen, under a variety of names, as *macroglossia*, *lingua vitulina*, or *propendula*, *providentia* or *prolapsus lingue*.

It is only within recent years that the affection has become the subject of careful clinical and histological research. Weber, whose exhaustive article in 'Pitha and Billroth's Handb. d. Chir.' may be referred to for the older references on the subject, was himself one of the first to describe the morbid histology of the condition.⁴ He was immediately followed by Virchow,⁵ who first really put its nature in a clear light. The latter was then followed by many other observers, among whom may

¹ *Med. Times*, vol. xii. p. 392.

⁵ *Ibid.* p. 120; also *Krankh. Geschouste*, Bd. iii. pp. 101, 203.

be specially mentioned Arnstein,¹ Billroth,² Humphry,³ Arnott,⁴ Maas,⁵ and quite recently by Wagner,⁶ all confirming his views, amplifying them somewhat, but not adding much to his main facts. The subjoined brief description then of the disease is chiefly based upon a careful examination of these more recent writings on the subject (the author's personal clinical observation extending only to two cases, in only one of which there was an opportunity of microscopic examination of the organ), the conclusions being drawn from a consideration of the whole mass of evidence before us.

The condition in question is characterised by an overgrowth of the tongue of greater or less rapidity, and affecting all its dimensions, sometimes to an extraordinary degree. Thus it has been found to measure as much as six and a half inches in length and ten inches in circumference. It may protrude far over the chin, and even into the episternal notch. When thus enlarged, it has been found to produce great deformity of the teeth and jaws, especially the lower, in a number of cases (Siebold, Humphry, *l.c.* Hodgson⁷) Clarke,⁸ Fergusson.⁹ The alveolar process is pushed forward, and the lower front teeth bent over into the horizontal position, if they have not been rendered carious, and dropped out, as is usually the case where the condition has existed long. The jaw has even been known to be eventually dislocated in extreme cases (Chalk¹⁰).

When thus swollen, the tongue is much altered in external appearance, though not so when but slightly enlarged. This is due to the accidents depending on its constant exposure to the air, the patient being unable to bring it into the mouth. The decomposition of the saliva and chafing against the teeth, &c., produce chronic irritation, and this leads to induration, fissures, and irregularities of the surface, and even to ulceration and scarring. In a case under the author's care for a time at University College Hospital, the appearances were precisely the same as those described by other observers. The uniformly hypertrophied organ looked more livid than usual; it was of a tough spongy texture, covered especially at the sides and under surfaces with small knotty semi-transparent elevations of conical or rounded shape, scattered irregularly. The enlargement was not accompanied by any pain, but was very troublesome from the flow of saliva produced by it; it was free from active congestion. When incised, it yielded very little blood, but a relatively large quantity of clear serosity. An attack of glossitis, produced by the introduction of a seton, only aggravated the condition. In another case in hospital at the present moment (June 1, 1880), under the care of one of my colleagues, the external appearance of the organ suggests little more than a general enlargement of all the elements of the organ, in its anterior two thirds. It can be retained in the mouth, and then only causes a fulness in the floor of the latter, where, too, an extra swelling of soft consistence, and about the size of a nut, may be felt. The boy has also enlarged fingers and toes, and is semi-idiotic. The condition is congenital, and he is now nine years old. The lower molar teeth are as yet but little deformed.

The first point, demonstrated by the study of the history of a large number of cases of macroglossia, is that the affection in the majority is clearly congenital. In Weber's¹¹ collection, embodying de Leuw's table of 69, and his own list of 27 cases, evidence on this point is forthcoming in a considerable number. Adding 17 cases since recorded and collected by the author, we find the following facts. The total of 113 was made up of 60 in which the disease was undoubtedly congenital; 39 in which it was apparently acquired, and 14 doubtful; 41 were males, 45 females, and of 27 there was no note on this point.

But, though the proportion of congenital to acquired cases is shown even by this table to be large, I cannot help thinking from the evidence before me that it would

be very much higher were all the records as minute upon this point as they should be; indeed, I have little doubt but that the affection would be shown to be congenital in all cases. For it has been noted in several instances where the child was seen shortly after birth by medical men that the tongue at that time appeared merely somewhat too large for the mouth, and projected a little against or between the teeth. Now such a condition might easily be overlooked for a long time by any but a practised observer, especially as the act of sucking appears to be of benefit for a time, owing probably to the pressure upon the tissues of the tongue by the nipple and the various movements of the organ itself. Moreover, it is also noted that not until dentition is advancing has the condition become marked in many cases. Taking this in conjunction with the fact noted, that the disease in numerous instances has apparently started from some violence, such as a bite during fits (to which for some unknown cause these patients appear peculiarly prone) or a fall upon the chin, as in Chalk's case, it appears not improbable that it has escaped notice in many cases in its earlier stages, and has not been recognised until the chafing of the sharp young teeth of first dentition, or a bite from them, had provoked a certain amount of glossitis, and thus aggravated the condition henceforth set down by the parents or other observers as distinctly acquired. That glossitis is one of the most prominent factors in the aggravation, if not production, of the extreme forms of the disease is clear from even a casual perusal of recorded cases. The causes for this inflammation, however, are often very slight indeed, showing by this alone that probably some congenital condition is predisposing the organ to inflame. Thus I find it starting in one case apparently from the small wound of an operation for ranula, and in others from division of the frænum (Möller,¹ Sédillot²), neither of which causes would have operated probably without strong predisposition. Other more marked proximate causes have been mercurialisation, senlatalinal irritation of the mouth, small pox, and erysipelas. Once the tongue is actually permanently protruded from the mouth, a chronic glossitis is often maintained by the exposure of the organ to various forms of irritation, such as cold, the chafing of the lower incisors (which also retard the reflux of the venous blood and lymph of the part), the dribbling and decomposition of the saliva and particles of food, &c.

From all this, it will be seen that the condition has a close analogy with elephantiasis in other parts, where a chronic irritation, with distension of the lymphatics, appears to lie at the root of the local change, but where a congenital enlargement of the parts, probably also dependent upon abnormality of the lymphatic system, can likewise be traced in some cases. In one of the more recently recorded instances of macroglossia indeed, half the body of a child was found hypertrophied at birth, as well as the tongue; the latter also more on one side than on the other (Maas³); and in a case now in University College Hospital, referred to above, the fingers and toes are also enlarged on both sides. In the former case an examination of the parts removed by operation showed, however, only a simple hyperplasia of all the elements of the tongue, without a preponderance of any, except in the cases of the vessels of the papillary layer. But here the patient was only two months old, and had not as yet had any inflammatory attacks.

But the analogy with elephantiasis appears even closer when we come to examine into the histology of the part affected. Almost all who have had an opportunity of studying the affection from this point of view have described essentially the same changes. Virchow⁴ was the first to notice these: namely, a remarkable infiltration of the whole organ, with innumerable white cells collected here and there within delicate networks, and forming thus a true lymphoid tissue. This was most abundant in his experience about the under surface of the organ, where it presented in parts a cavernous structure. This tissue had hardly the regularity of arrangement found in that of the lymphatic glands; but the same delicate reticulum containing lymph spaces were observed. The small semi-transparent elevations on the surface of the

¹ *Deutsche Klinik*, 1851, No. 20.

³ *Archiv f. klin. Chir.* Bd. xiii. p. 419.

⁴ *Krankh. Geschwülste*, Bd. iii. pp. 101, 203; also *Virchow's Archiv*, 1854, p. 126.

organ described above were due to the latter, which in many cases consisted of channels with saccular dilatations. The connective tissue, too, throughout the tongue was everywhere greatly increased in amount, especially immediately underneath the mucous membrane.

One of the most recent and careful observers of the lymphangiomata (Wegner¹) departs, however, a little from Virchow in denying the infiltration of the hypertrophied part with lymphoid cells. The fact of his having apparently only examined early cases of the disease, little or not at all altered as yet by attacks of glossitis, suggests, however, an explanation of this difference. He also describes openings from the lymphatics into the venous radicles when the disease is well marked, and consequent entrance of blood into the lymphatic channels. In some cases (Weber, Grohe, Busch²) the muscle-fibres were said to have been increased in volume, but not in number: this, however, has not been confirmed by other observers. The large cavernous spaces alluded to contained clear lymph of the ordinary kind, and sometimes blood. But, beside these irregular dilated channels, the veins and arteries have been found generally enlarged in calibre, and somewhat thickened also, adding much to the spongy texture of the part. In one remarkably acute case, described by Virchow,³ the glands under the jaw were simultaneously enlarged, and on puncture yielded several drachms of clear lymph-like fluid. Again, in a case from which drawings were taken by Whitehead,⁴ not only was there congenital macroglossia, but also a dilatation of the lymphatics of the neck, to the extent of producing actual cystic lymphangiomata. It is, perhaps, also worth noting that in one case recorded by Valenta,⁵ the enlargement of the tongue was associated with cystic hygroma of the neck.

The terms, then, *lymphadenoma cavernosum* (Arnstein l. c.), or *lymphangioma cavernosum* (Virchow), appear to be very suitable for this condition, especially as either of them will also cover Billroth's⁶ views as to the changes met with, which indeed correspond in the main with Virchow's, except that he held the lymph-spaces found by the latter observer to be new formations, rather than dilatations of pre-existing vessels. This may be considered now, however, perhaps a distinction without a difference.

As to *causation*, we have already seen the influence of congenital fault followed up by attacks of glossitis. These last may probably more accurately be described as sub-acute or chronic lymphangitis, predisposed to by some obstruction to the return of the lymph towards the root of the organ, congenital and in part acquired. There seems much reason indeed to regard Billroth's view on this point of *etiology* as most probable: namely, that the attacks which have led to successive enlargements of the organ have been caused by a thrombotic change in the dilated lymphatics of the part, with consequent swelling of the distal portion; and that the predisposition is given, at all events in part, by the inherited scrofulous diathesis. This view gains some support from the fact that many of the attacks spoken of in these cases as glossitis are in reality far less acute than that disease usually is, and further, that in some cases (Möller's, Billroth's) after removal of the diseased portion of the tongue had been followed by recurrence of the swelling, the use of cod-liver oil, iodine, and preparations of iron, alone or in combination with other anti-strumous remedies, has been quite adequate to the treatment of the affection, the organ returning to its normal size, just as a strumous gland will do. But our present clearer knowledge of the nature of the disease, and wider experience of its usual course, teach us that we cannot expect this always to be the case. Anti-strumous remedies may retard, perhaps arrest, the advance of the condition for a time; soothing and detergent solutions may remove causes of irritation; but the congenital derangement of the tissues, and predisposition apparently to lymph-stasis in the part, remains, whether this be due solely to proximal narrowing of the lymphatics at the root of the organ,

¹ Arch. f. klin. Chir. Bd. xx. p. 461.

⁴ Internat. Med. Congress, 1881, Catalogue of Temporary Museum, p. 69, No. 597.

⁵ Oesterr. Jahrb. f. Pädiat. Bd. ii. s. 35. ⁶ Beiträge z. path. Histolog. 1868, p. 215.

or this combined with occasional thrombosis in the same situation. Sooner or later the organ is almost sure to be irritated, and it usually is so at the commencement of dentition when the edges of the sharp young incisor teeth rise out of the gums. The slight congestion thus produced will lead to greater obstruction of the lymphatics, and chronic and increasing thickness is the result.

These then are the considerations which impel us in most cases to resort to operative measures for the relief of the condition. But we now know that some of the older methods ought to have been as they were, productive only of harm. Among these were, the use of setons drawn through the tongue, injection of astringent fluids. These and like measures resorted to on the mistaken belief that thus the spongy tissue of the organ could be consolidated by inflammation or coagulation, can only be productive eventually of glossitis in one form or another, and instead of effecting the purpose intended, only produce increased lymph obstruction and swelling of the whole organ. This I have seen in one case at least.

There remain, then, only two or three other methods of treatment. Pressure in one form or other has been long employed, and in a few instances has been found of use. Thus, where the tongue could be pushed back into the mouth, and the chin then supported by an elastic band, some benefit has followed (Taile¹). Again, in more advanced cases the organ has been included in a tight linen bag tied back with tapes behind the head, also with improvement. Strapping with isinglass plaster has also been used. But, although in theory such treatment is rational, tending as it does to unload the engorged lymphatics and blood-vessels of the tongue, just as bandaging and pressure on a limb affected with elephantiasis would in the latter, still practically we are met by great difficulties in carrying out our treatment; and the study of such cases is not encouraging. It only strengthens the conviction now generally gaining ground: namely, that the only method of treatment adapted to the mass of these cases is excision of the bulk of the hypertrophied organ. But there is one point in connection with this question that should never be forgotten: namely, that for this operation to be quite safe it should be performed before the tongue has enlarged inordinately, or to such an extent as to leave a large wound in the mouth after incision, with all its peculiar dangers of septic infection, to which allusion will be made later on, in considering the various modes of removing the whole or parts of the tongue (p. 590).

While awaiting the proper time for excision (for this should not be done while the child is very young, or indeed until the condition shows unmistakable signs of steady growth), it is well to suckle the infant from a large teat, so as to produce all the pressure possible upon the organ. This may retard its growth somewhat for a time, and so enable us to postpone a serious operation until an age better suited to bear it. When dentition introduces new factors of irritation, it is not judicious to defer interference any longer in most cases. The deformation of the jaw may then be prevented from taking place. If, however, a case is brought to us in which this has been allowed to take place to a moderate extent only, we may, after removal of the tongue, benefit the deformity to a large extent by exerting upward pressure on the chin by means of an elastic band passed under it and then fastened over the vertex. Later on when the jaw has become fully developed, it is almost vain to hope for much improvement from this treatment.

INFLAMMATORY AFFECTIONS.

1. *Superficial non-ulcerative.*—The inflammatory affections of the tongue have now to be considered. They may be classed into (1) the superficial non-ulcerative; (2) the ulcerative; (3) the parenchymatous. Any of these may be acute, sub-acute, or chronic.

Of many of the changes in the superficial layers of the lingual epithelium symptomatic of disordered states of the alimentary tract, and partaking of the nature of an irritation of the coverings of the organ of one kind or another, nothing special need be said in a surgical essay, however interesting they may be. An excellent

¹ *Trans. Med.-Chir. Soc.* vol. xxxvi. 1853.

description of them will be found in a lecture delivered by Dr. G. V. Poore at University College Hospital and published in the 'Lancet' of 1880.

Nor is it necessary to enter into a description of conditions due to the presence of the parasites known as the *oidium albicans* and *leptothrix buccalis*. These are fully dealt with in medical books, and need not occupy us. That the mouth is infested with numerous lower organisms in certain conditions is well known, but it is not always as clear what the relation of these to the morbid state is, as in the case of the parasites just alluded to. Thus spores indistinguishable from those of the *trichophyton tonsurans* have been found on the tongue without any evidence of disease. Also numerous forms of micrococci in great abundance. The study of these offers a large field for future investigation. On the other hand, the presence of certain cryptogams has appeared in given cases very suspiciously associated with unusual conditions of the surface of the tongue. For instance, the *trichophyton* has been found together with a peculiar 'villous change' on the epithelial covering of the organ (Clauke). This parasite has even been present in cases where a peculiar circular wandering rash had made its appearance on the tongue deceptively like 'ringworm,' and yet probably without any causal relation to it, so far as we know. This latter condition is so apt to be mistaken on the one hand for a parasitic disease, and on the other, for some syphilitic affection, that we may perhaps with advantage direct the attention of surgeons briefly to its peculiarities as far as they are known at present.

These circular wandering rashes have attracted a good deal of attention lately, not only owing to their very striking characters and their resemblance to *tinea tonsurans*, but equally on account of the discomforts associated with them.

The author's interest in them is peculiar, having been greatly puzzled in their diagnosis some years ago, and in finding then that they had not been specially described before in this country. Referring to a paper on his first two cases read at the Path. Soc. Nov. 1879 (vol. xxi. p. 353 of 'Transactions') for details, a short account of the disease

FIG. 132 represents the *Annulus migrans* in its well-developed form, as well as at its very commencement.

Above on the dorsum of the tongue are seen the two crescentic bands of rash spreading centrifugally and leaving a smooth some what darker surface behind. Below are two spots at which the affection is starting afresh, soon to develop either into rings or crescentic bands travelling with great rapidity.

may be given here. It may be added that a few months after this paper was made public, some independent observations were recorded by M. Vanlair¹ in France on the same disease, and, later still, by Professor Caspary² in Germany, also independently. These three essays, with a short incidental notice by Gubler,³ recording 11 cases in all, appear to constitute the whole special literature of the subject hitherto.

This affection, for which the name *annulus migrans* or *errans* was suggested by the author (*l. c.*) as sufficiently descriptive, while involving no theory in regard to its ætiology, and therefore perhaps preferable to that of 'lichenoid of the tongue,' used by Gubler, is characterised by the appearance on the tongue of small circlelets or crescentic bands of light-coloured rash. These enlarge rapidly and wander from place to place centrifugally over the dorsum and occasionally the borders and under surface of the organ. Its close resemblance to *tinea circinata* is the first point which strikes the observer (fig. 132), the extreme rapidity of its movements the next, the remarkable amount of salivation accompanying it the next, and, finally, its stubborn resistance to all local or general remedies. Commencing as a small round spot of a whitish or greyish-yellow colour, it rapidly develops into a more or less complete circle or crescent (see fig. 132), of

granular appearance, abruptly marked off on its convex margin from the healthy surrounding surface. That portion of the dorsum lying within the concave margin

¹ *Revue Mens. d. Méd. et de Chir.* Jan. 1880.

² *Vierteljahresch. f. Dermatol. u. Syph.* 1880, Heft ii. and iii.

³ *Dict. encyclop. des Scien. méd.* t. x. 1^{re} partie, p. 234.

of the narrow band of rash, i.e. that last travelled over, is smoother and of a livid pink colour, but shows no trace of excoriation or ulceration, and frequently recovers its normal appearance in the course of a few hours. No pain accompanies the disease, but sometimes a little smarting in the use of particular kinds of food is noticed. In one of the author's cases intense itching and salivation lasting for months were noticed, in the others both symptoms were present in a minor degree. Of the 11 cases recorded, 5 were males, 6 females; 9 were under 20 years of age, 7 under 10 years, 1 was 66; in 4 the father had been clearly syphilitic, in 4 clearly no syphilis appeared in the family history, in 3 no record is given on this point.

Ætiology.—The first point which has occurred to all observers as to its causation has been its probable parasitic origin. Up to the present no post-mortem specimens have been obtained, scrapings of the diseased patches alone having been available for study. Careful microscopic examination of these has convinced the author that it has no relation to 'ringworm.' On one occasion certainly he found cryptogamic organisms in abundance, indistinguishable either by himself or Mr. Hutchinson, to whom he showed them, from the *trichophyton tonsurans*. But these were only met with on one occasion out of a great many observations and were most probably accidental. The same may be said of large aggregations of micrococci and other organisms observed, which were also seen by the author and by M. Vanlair, and were figured by the latter, who with Caspari takes the same view of the non-parasitic nature of the affection. Both these observers are also in accord with the author as to the independence of the disease on syphilis. No local irritation was present in any case or intestinal irritant proved. It appears nevertheless, comparing it with similar appearances, to be probably one of those degenerative changes of the superficial layers of the epithelium brought about by nerve influence, the result of reflex irritation somewhere at a distance. This is a point which can only be determined, however, by further and closer study, and it appears better for the present to adopt some name for the condition generally descriptive, but not involving any theory as to its ætiology.

Treatment.—No treatment has as yet produced any effect on the cases recorded. In my own, tonics, cod-liver oil, iron, arsenic, local applications of nit. of silver, chlor. potass, &c., were all given a prolonged trial, but without the slightest effect.

Prognosis.—Beyond being very chronic there appears to be nothing to fear from the affection but the discomfort and itching described; no other dangerous sequelæ having ever been noticed, even where the affection has lasted for years, as in one of the author's cases which he has followed up to the present.

From these irritative conditions of the most superficial layers of the epithelial coverings of the tongue we turn now to the more distinct inflammatory.

Acute superficial non-ulcerative glossitis is not a common affection. When met with it is usually the result of scalds, burns, or the application of some very irritating substance to the surface of the tongue. The latter in such a case will appear in the first instance flecked with whitish patches on a red ground. These white patches correspond to areas of epithelium which are being shed off from the inflamed surface. The latter, then, will have soon lost large tracts of its covering and will appear glazed and reddened, with prominent papillæ, and will be very sensitive, owing to the greater or less exposure of the latter without their usual covering.

The treatment will consist in restricting the patient to fluid food of an unirritating kind and giving him ice to suck. The condition, if it have gone no further than above described, has a tendency to get well rapidly of itself, and beyond the treatment indicated requires little.

Sub-acute and chronic superficial glossitis of the non-ulcerating form are, however, by no means uncommon, and constitute an important class of diseases.

The causes here are usually external in the form of local irritation of one kind or another. This may be due to the constant over-stimulation of the surface of the tongue by too hot food, the excessive use of spices, the abuse of ardent alcoholic fluids, the chafing of teeth roughened either by decay or a coating of foul tartar, the play of the tongue against ill-fitting false teeth, finally, by the over-use of tobacco, either chewed or smoked. There is reason to think, however, from the study of

certain recorded cases that somewhat similar, if not identical, conditions can be produced, or at least strongly predisposed to, by causes operating from within at a distance, such as irritation of the gastro-intestinal tract from varieties of indigestion, or, possibly the presence of parasites, such as tapeworm (Möller l. c.).

The appearances presented in the earlier stages of *sub-acute* superficial glossitis produced in any of these ways will usually be as follows:—There will usually be congestion of the surface of the tongue over a larger or smaller area, on which the papillæ will be prominent and excessively sensitive. Or, a little later, the irritated patch may be covered with vesicles or desquamating whitish epithelium which, on being respectively ruptured or shed, leave an inflamed raw or glazed base, also acutely sensitive. This condition has a natural tendency to rapid recovery if the cause be removed, owing to the highly organised structure of the tongue. It is only necessary, then, for its treatment to find out the local irritant and remove it, and at the same time keep the tongue cleansed for a while. If the cause be suspected to lie in the gastro-intestinal tract, attention to the diet, with the use of alteratives, antacids, and laxatives will usually be found to benefit.

In the more *chronic* forms of superficial glossitis, due to one or other of the causes mentioned above operating over extended periods, peculiar permanent changes take place in the epithelial covering of the tongue in many instances which deserve particular study. In the first place, slightly raised, glazed, and reddish patches are developed on one or other part of the organ, most usually the dorsum. These are due simply to a localised hyperæmia of the papillary layer of the tongue. As a consequence of the prolonged existence of this increased vascularity, the epithelium sooner or later becomes thickened, its most superficial layers furthest from the blood supply undergoing keratinous changes. In this way patches of hypertrophied and now whitened epithelium soon more or less obscure the colour of the vascular patches over which they are formed. These plaques generally attain a considerable size before being noticed by the patient, for they are not painful, do not affect the sense of taste, and only in some advanced cases are accompanied by increased flow of saliva, nor are the glands under the jaw in any way affected by the condition in uncomplicated cases.

Much attention has been given to this condition in its various stages of late years, and it has been described from time to time under many names—e.g. *plaques opalines*, *plaques des fumeurs*, *psoriasis lingue*, *ichthyosis glossæ*, *keratosis*, *tylosis*, *leucoma*, and *leucoplakia*. These are only mentioned here for the purpose of adding that they all mean the same condition, and that this is initiated by a chronic superficial glossitis as above briefly described. The last name applied to the affection will recommend itself to many in this country who would willingly avoid the fallacy of implying its analogy with other fully investigated skin affections by the use of a name borrowed from dermatology, or dislike the use of a word indicating a supposed special cause. This word *leucoplakia* is suggested by Schwimmer,¹ who in the most exhaustive and interesting description of the disease yet published has analysed his own numerous observations as well as those of almost all the authors who have preceded him. He has traced the disease from its first appearance in the form of slightly elevated, dark red, and smooth patches on the mucous membrane, the result of 'congestion of the deeper epithelial layers with consecutive hyperplasia of certain tracts of papillæ,' to that of the bluish-white plaques described above, and even beyond this to those ultimate degenerative changes into malignant disease which are now known to supervene sooner or later in only too many cases. For a minute and detailed description of the morbid histology of the condition the reader is referred to the essay, by Schwimmer, mentioned above, and to another by Nedopil.² It is only necessary to say here that the disease, if seen early, presents itself in the form of small hyperæmic spots of dark red colour situated on any part of the tongue, lips, palate, or cheeks, but most usually on the dorsum of the former and near the angle of the mouth in the latter. This condition, of which I have seen a particularly striking example lately, should be studied carefully with a view to early treatment. These, spreading and

¹ *Vierteljahresschr. f. Dermatol. u. Syph.* N.F. 1877, p. 511.

² *Archiv f. klin. Chir.* Bd. xx. 1877, p. 324.

coalescing, eventually form considerable plaques, which by this time have become of a pale bluish-white or dead-white colour. In this stage the tongue looks as though it had been brushed over certain areas with a solution of nitrate of silver; but the surface is here still soft and even. Now as long as there is a narrow border of erythema around these white patches they may be regarded as on the increase; if this is absent, active growth has come to a standstill. Later on, then, the plaques may become greyish-white or sometimes yellowish, and their surface marked by intersecting depressed lines. The presence of the latter is due to the hardening of the epithelial covering of the tongue, which has now taken place, destroying its general pliancy, and necessitating a wrinkling with every movement of the organ. In some very advanced cases the epithelium may become so hardened as actually to

FIG. 133.—A part of the Plaque under a higher power. (Object 9 immersion: camera lucida.)

a, thickened keratinous layer of a highly developed part of a plaque; *b*, keratinous layer above small-celled granulation with some bright bodies (*c*); *d*, granulation-cells advancing into the epithelium from the neighbourhood of a markedly proliferating papilla (*e*); *f*, lateral boundary of the small-celled granulation (exudation); *g*, inferior boundary of the epithelium, whose cells are partly thrust asunder by exudation springing up from the mucous layer; on the right (of the figure) they are flattened; on the left destroyed by the fine-celled exudation; *h*, a vessel in the submucous tissue, from which on the left there springs a twig (*i*), surrounded by dense granulations, and stretching into the fine-celled exudation.

crack and split along these lines, and may then scale or be peeled off in fine layers. All such changes are due simply to different degrees of keratinous alteration of the epithelium, induced by chronic irritation modifying its vascular supply (fig. 133, 134).

When the disease is well marked, a notable change is found to have taken place in the papillae of the tongue, beneath the white patches, as seen under the microscope. These, which at an early stage were hypertrophied and infiltrated with leucocytes (fig. 133 *e*), are now atrophied as regards all their elements, or have wholly disappeared (fig. 134 *c*, *a*). In the layers underlying them, exudation of cells is still seen along the vessels (fig. 134 *d*), and the tissue, to put it briefly, is generally sclerosed.

Now when this condition of leucoplakia has lasted for a longer or shorter time, and the heaping up of keratinous layers of epithelium has gone on to an extreme degree, other changes in the epithelial covering are very apt to arise and to result in epitheliomatous cancer. Briefly, the cells of the deeper layers commence to

proliferate more rapidly than usual, spread downwards into the substance of the tongue in the form of rapidly enlarging lobules, until the well-known characters of epithelial cancer are clearly present. This overgrowth may or may not be preceded by slight chronic degenerative ulceration of the white patches. In those cases where cancer followed on leucoplakia seen by the author, this ulceration usually preceded the malignant degeneration, and the latter appeared on the whole rather slower in its advance towards infiltration of the surrounding structures and glands than epithelioma starting in other ways (see p. 592).

When all this malignant change is about to take place, or whether it is going to begin at all in any given case, are points which cannot be determined positively as yet from any known premonitory signs. It can only be said that the condition is always a suspicious one, and to be regarded with anxiety whenever it exists, especially if it be accompanied by ulceration. The latter complication, indeed, must be looked upon as constituting the affection a most grave one, which should be dealt with by free and early excision, if it be found that there is any induration present with it.

FIG. 134.—Section of a portion of Tongue affected with Leucoplakia.

a small cell granulation representing the exudation at the boundary line of the epithelium, b thickened epithelium of the plaque proper, c cell proliferation in the papilla body most evident at the tip. To the right of c for a considerable space all the papilla bodies of the mucous layer are seen to have been destroyed, d vessel in the corium around which for the most part the small celled infiltration has taken place, e granulation cells in the corium, f mucous glands with proliferation in parts, g relatively normal epithelium with perfectly sound papillae.

This disease, frequently noticed during the last fifty years, was supposed by its earlier observers to be the result of syphilis (Babington Wallace). Other writers described it as connected with or part of a general ichthyosis, only most marked on the skin (Plumbe,¹ Alibert,² Rayet³). Later on it was recognised by Buzenet⁴ and Ullmann in 1858 as a condition independent of skin affections and of syphilis, and as probably produced by smoking, and was named by the first of these writers 'plaques des fumeurs.' But the chief interest of the affection dates from the observation of the fact by Mr. Hulke⁵ in 1861 that it may be the starting point of epithelioma, if not its sure precursor, as already mentioned. The conclusion that this is so was also arrived at independently a little later in 1862 by Neligan⁶ of Dublin, who published a very remarkable case of the condition and the development in it of epithelioma, with the object of drawing the attention of insurance consultants to the significance of the latter fact. From this time to the present the affection has attracted much attention, chiefly as regards the following points, viz. (1) its causation, i.e. whether due to syphilis, smoking, or other local irritations, or the same diathesis which pro-

⁵ *Dublin Quart. Journ. of Med. Science*, 1862.

duces ichthyosis or psoriasis of the skin; and (2) its *exact relation to epithelioma* i.e. whether simply predisposing to the disease or inevitably followed by it.

In studying this disease in its various stages specially for myself for some years past, I have been at much pains to collect as many cases as possible from home and foreign sources, in which these white patches have been described as found on the tongue or other parts of mucous membranes, and to tabulate them in such a manner as to afford evidence on these and other questions. This table, including several cases from my own practice, together with others recorded by the authors whose names and records on the subject are given below,¹ now offers 96 cases for study. While correcting this for press I have, through the kindness of Mr. Henry Morris, been furnished with notes of an additional 14 cases which have been under his own observation, and have much satisfaction in adding them to the above.

We have then a total of 110 cases before us for analysis. Of these 101 were males, 9 females. Among the former the affection was seated on the tongue in 55, on the tongue and cheeks in 33, on the lips and cheeks in 12, on the hard palate alone in 1, and in 4 the seat of the affection is not given. Among the females the tongue was affected in 7, the vulvæ in 1, the lips and cheeks in 1.

As to its *ætiology* the following data are afforded by the above collection of cases. In the first place its relation to *syphilis* may be considered. Distinct evidence of these patients having suffered from concomitant syphilis is forthcoming in 33 cases; it is distinctly negatived in 19, no history of it is given in 32, and no statement on this point in 19; in 1 it was probably present and in 1 doubtful, while in 2 it was contracted after the white spots had appeared. That leucoplakia may occur quite independently of syphilis appears therefore perfectly evident from 19, if not from the additional 32 cases. These hard statistics, however, will not at present settle this matter beyond question. But the internal evidence of the cases themselves, including those I have seen, leads, when read carefully, to the conclusion that these white spots appear in patients who have never had this disease. There are, however, syphilitic affections very like that in question in its earlier stages (see p. 570).

As to the relation of *smoking* to its causation evidence is forthcoming in 75 cases. In only 4 is it distinctly stated that the patients did not smoke, in 11 that they simply 'smoked,' in 14 that they did so in moderation, and in 46 that they indulged in the habit to excess. There are then 71 smokers to 4 non smokers. We must not forget, however, that the disease showed itself in the female in 9 cases (presumably non smokers), and in 1 case it appeared on the vulvæ, where it developed into epithelioma within 18 months; in the remaining 8, on the tongue in 7, the lips and cheeks in 1, with cancerous change in 2. There can be no doubt, however, that, though it may arise independently of smoking, the latter habit was the proximate cause in the majority of cases hitherto observed.

As to its *relation to other skin affections*, ordinary psoriasis or eczema was a concomitant in 6 cases, syphilitic psoriasis in 2. Ichthyosis has also been seen associated with it in more than 1 case.

Besides all this, there is evidence in several of the cases before me that the affection may be produced by other irritants introduced into the mouth habitually, such as the hotter variety of spices, ardent spirits, &c., as in a case at present under my own treatment. The chafing of irregular or false teeth has also apparently been at the root of the affection in other cases.

The most important question now arises, namely, its relation to epithelioma. On this our list furnishes the following data. In 43 cases (probably in 1 more) epithelioma supervened upon the condition. Of these a family history of cancer is only given in one case. It had existed before the development of malignant disease for periods ranging in several cases from above 30 and 40 years down to 15 months,

Quart. Journ. of Med. Science*, 1862; Hulke, *Trans. Clin. Soc.*, 1869, *Med. Times and Gaz.*, 1861, 1864, 1873; Morris, *Brit. Med. Journ.*, 1874; Weir, *New York Med. Journ.*, 1875; Nedopil, *Archiv f. klin. Chir.*, 1877; Trelat, *Bulletin de la Soc. de Chir.*, 1875; Schwimmer, *Viertejahressch. f. Dermat. in Syph.*, 1877-78, and others.

which is the earliest date of appearance of epithelioma noticed after the white patches first appeared. Taking 29 cases in which data on this point are given, the average time for the supervention of cancer on the condition was 14 years and a fraction. Only in one patient (æ. 24) has cancer supervened on leucoplakia before 35 years of age. From 35 to 45 it has done so in 7 cases; from 45 to 55 in 17; and from 55 to 65 in 13; after that age only in 2 instances. These white patches have made their first appearance at ages ranging from 16, 18, 19 to 69.

Taking these facts into consideration, we have a certain amount of evidence that the disease is, in some cases at all events, a precursor of epithelioma. But, on the other hand, that it cannot be regarded as certain to develop into this disease, seeing that it has lasted, in some instances, as long as thirty or forty years with no trace of malignancy. It must also be remembered that probably only a small proportion of the individuals who are affected with this complaint come under medical notice, many of those in the above list having sought relief only on account of the development of the cancer. It is also worth noting that the latter has appeared in these cases most frequently at the same ages at which cancer, without any leucoplakia, is most frequent (see p. 590).

But so much at all events is learned from these facts—namely, that the existence of the condition should always lead to a careful examination of the tongue from time to time in search of any possible traces of spreading induration under the surface, which should at once be removed by free excision. Also that with such a condition the patient should be warned against all avoidable irritation of the tongue, and of the necessity of careful and prolonged treatment in the direction of allaying such as may exist, whether it be local or reflex, and of softening and removing by easy stages the thickened masses of keratinous epithelium of the white patches.

This treatment will consist then in abstention from the use of tobacco, either smoked or chewed, as well of all kinds of spices or hot solids, fluids, or raw spirits. Then the teeth must be constantly attended to for the removal of all rough edges or tartar, the mouth being regularly and carefully washed. For the latter purpose the most suitable fluid is a solution of Bicarb. Sodæ of the strength of twenty grains to the ounce of water. This should be used frequently during the day and allowed to rest around the tongue for long periods. In two cases now under my care I have noticed first great increase of sensitiveness of the tongue under the use of the above soda wash, and then some considerable improvement of the condition. The use of caustics cannot be too strongly deprecated; they can only aggravate the condition. Washes of Bichloride of Mercury, $\frac{1}{2}$ per cent., or of Chromic Acid of 1 per cent., are also recommended by Schwimmer¹ and Hilliaret,² but the author would trust rather to the soda solution.

But if the disease produce any nodular induration of the tongue, and any of the plaques become the seat of a slight discharging fissure or ulcer at the hard point, surgical aid should be at once invoked, and the condition be dealt with as one of epithelioma. In such cases we should not wait for the development of a distinct cancerous nodule, for it may and probably will be absent from the first, its place being taken by a shallow rugged induration spreading around the fissure alluded to.

As to the question of operative interference in the earlier stages of the disease before induration or breach of surface have taken place, it is negatived by many of the facts cited above—namely, that the disease has existed in several cases harmlessly for over thirty and even forty years. In face of this fact it would be rash to prognose the supervention of epithelioma, and to operate at once in all cases; but our other facts above indicate with what extreme care and suspicion the disease should be watched, and how promptly it should be dealt with if it show the slightest tendency to proliferation downwards of the epithelium. Here the only proper treatment is partial or complete excision of the tongue (see p. 600 *et seq.*)

Somewhat allied to the last affection histologically is another condition known to many surgeons as the 'glazed red tongue.' It is chiefly of importance to be familiar with this condition, from the fact that it, too, is often observed as the precursor of epithelioma. I have quite recently removed a great part of the tongue from a male

¹ *Trans. Internat. Med. Congress*, 1881, vol. iii. p. 173.

Ibid.

set. 62, in whom the condition was well pronounced. Here the surface of the organ was marked by irregular patches of a glazed red appearance, as though denuded of their topmost layers of epithelium; they are not indurated in the least, but are rather abruptly defined against the rest of the tongue. The condition is most seen near the borders of the anterior part of the organ, and is pitted in one part and perhaps raised in another. It is not painful, and may not be noticed by the patient for a long time. It is apt, however, sooner or later to become the seat of small irritative blisters or very small abrasions or ulcers, one of which, too, frequently becomes indurated at its base, and develops into a nodule of epithelioma, as in the case above mentioned. It does not appear to be due in any way to smoking or syphilis, and its ætiology requires further study. It appears probable that it may correspond to the earlier stages of leucoplakia as described by Schwimmer, the heaping up of keratinous epithelium not taking place for some unknown reason.

2. *Ulcerative*.—We have now to consider the ulcerative inflammations of the tongue; and first those due to *local* irritation, of which there are several.

First, that produced by the irritation of the sharp edge of a decayed tooth, or one coated with tartar. This is usually an abrupt irregular depression seated on the border of the organ with a zone of inflammation, but with little or no induration around it. The surface is generally covered with white or greyish pus, and is acutely sensitive; the movements of the tongue, too, produce a sharp cutting pain at the spot. The lymphatic glands under the jaw are not enlarged as a rule.

The cause of this ulcer is usually easy to discover, and its removal, either by cleansing or extraction of the offending tooth or filing down of the sharp edge, is often followed by rapid healing. If this be not the case, the use of Chlorate of Potash washes of the strength of gr. x. to ʒj. of water will generally help the process materially.

The same form of ulcer may result from the irritation of badly-made false teeth, or may follow on a bite of the tongue or the chafing of the rough stem of a pipe. In the latter case the ulcer is inclined to be more chronic, and, consequently, to have a trace of induration about its base. The same may be said of the sore which often follows the smoking of an unusual amount of tobacco, which is inclined to be indolent. In all these cases, however, if recent, the withdrawal of the exciting cause, with the use of the above mouth washes, will suffice for a cure. These ulcers should be very carefully watched, for there is always a danger of any one of them developing into epithelioma, especially in patients in middle life.

The ulceration caused by the excessive use of mercury is perhaps less common upon the dorsum of the tongue than on its under surface and the rest of the cavity of the mouth. It appears to be due to over-stimulation of glandular structures of the latter, and is not difficult to recognise. In moderate degree it presents the appearance of shallow irregular patches with a red border suppurating freely; in more advanced cases the surface of the ulcer is soft, pulpy, and much depressed as a consequence of the sloughing action, which is considerable. The appearance of the ulcer, and the state of the other parts of the mouth, together with the salivation and great fœtor present, and the knowledge that mercury is being taken, can leave little doubt as to the nature of the condition, unless, indeed, the drug have been administered for syphilitic ulceration of the mouth, when it is sometimes a little difficult to say exactly how much is due to the disease and how much to the remedy. Discontinuance of the latter, however, will soon clear up any doubt, especially if washes of chlorate of potash be freely employed for the mouth, and the patient receive a few hot baths, fresh clothing, and change of air. Under this treatment the mercury is soon excreted from the body (especially if the bowels are acting freely as is usual) and the ulcer soon heals. Sometimes, however, as a consequence of this destruction of tissue, a contracted cicatrix is formed, and the tongue is bound down more or less to the floor of the mouth. This condition, sometimes spoken of as *ankyloglossa*, when it is complete, though strongly resembling, is very different from that in which the borders of the tongue are level with the floor of the mouth, simply because the organ has failed to rise from the latter in the course of development (see p. 555).

And when it is found in young patients we should carefully examine the whole mouth and the history lest we should fall into the error of operating on a congenital defect of the kind. Where the tying down of the tongue is due to the cicatrisation described, a little dissection will usually free the organ again, and attention to the healing of the fresh wound and stretching of its base with the finger daily while cicatrising will prevent it from recontracting, though not always.

Besides these ulcers due to local irritation, there are others depending upon *constitutional states* which must be considered.

First, there is the little ulcer of gastro-intestinal irritation often called the aphthous ulcer. This is most frequently found in unhealthy children as the result of ill feeding with acid foods, *e.g.* fermenting milk, sour bread, &c. It is also met with among young adults during attacks of indigestion accompanied by acid eructations, &c. It is usually seen on the border or under surface of the tongue in the form of a small punched-out circular depression with a white base and an abrupt red margin. It is produced by irritation of one of the mucous follicles of the tongue, and is therefore most frequently met with wherever these are most abundant—viz., under surface of the tongue, lips, and cheek. The pain produced by these little lesions, for they are usually multiple, is usually sharp and cutting, and quite out of proportion to their importance otherwise.

The treatment will consist in attention to diet, the use of antacids and alteratives, such as the grey powder for children, with tonics, then Chlorate of Potash washes for the mouth. These ulcers usually heal readily when thus treated, disappearing as fast as they come, often in a few hours.

Sometimes, as the result of very insufficient and ill feeding and the neglect of cleanliness of the mouth and teeth, these little ulcers appear in an aggravated form and spread freely until they become confluent. This form of *stomatitis* is not unfrequent on the gums and under surface of the tongue, the movements of which produce much pain. Owing to this the patient is debarred from the use of solid food, and the condition is thus often aggravated by the want of it. The fetor and discharge from the ulcers is also very hurtful to the general health. This condition calls for the same treatment as the last, and is usually easily managed. If it be neglected it may give rise to ankyloglossa, which may call for operation as already described. Although usually met with among children I have not unfrequently observed it among adults in a very advanced degree.

The *stomatitis* of scurvy is often, too, found within the mouth. It closely resembles the last described form, and hardly therefore requires a special description. The treatment moreover will be practically the same.

The tongue is also sometimes, but rarely, attacked with extensive ulceration during the specific fevers; generally this is quite superficial, but cases have been described in which the organ has been totally destroyed during small-pox.¹

Certain other forms of ulceration due to the breaking down of new deposits in the substance of the tongue will be alluded to in a later section devoted to the consideration of the neoplasms found here.

3. *Parenchymatous inflammation* of the tongue is perhaps the rarest form of the inflammatory affections of the organ. Its causes are manifold. It is not often, however, due to local irritation, but is rather the result of more general influences. In the greater number of cases it is produced either by the effects of mercury going beyond the provoking of ulcers as described, by exposure to severe cold and damp, or by the introduction into the mouth of irritating or septic matters. More rarely it is met with in the course of the specific fevers.

However caused, the effect upon the tongue is generally much the same in each case. One on both sides of the organ commences to swell rapidly, and frequently to the extent of protruding from the mouth. As it presses against the teeth it becomes indented and irregular: its surface is of a livid colour, smooth and glazed where it lies within the mouth, but brown and dry where exposed to the air. There is usually besides a very free secretion of saliva, which dribbles from the mouth in large quantities.

¹ Roland, *Aglossostoma'ie*, 1630.

Pain is not so marked as might be expected, but there is much distress from impeded deglutition and respiration, which may run on to an extreme degree. When the inflammation runs very high the tongue becomes deeply livid or nearly black, and may even slough in part or entirely. Occasionally one side of the face is swollen at the same time.

The rapid swelling in all cases is probably best explained by inflammatory exudation pressing upon the veins and lymphatics about the root of the tongue and preventing the reflux of blood and lymph from the part. It is easy to imagine this occurring in the case of exposure to cold where the glandular structures at the root have become affected. Or, again, where the tongue has been poisoned directly (as in the case cited by Clarke, where a butcher wounded the part with a foul knife while holding it between his teeth) the enlargement of the lymph-glands about the root would give the obstruction. But in other cases it is not quite clear what the course of events in the process really is, as, for instance, in the acute fevers.

The local treatment of acute parenchymatous glossitis is, as a rule, simple. Without making any allusion to the older methods, it may be plainly stated at once that the plan which has now gained the general favour is that of free scarification or incision. The use of leeches is followed by considerable benefit, but the knife will do all that they can do much more rapidly and effectually and with less suffering to the patient. It is used as follows. A curved, sharp-pointed bistoury is guarded with a strip of sticking-plaster to within half an inch of its point. This is then thrust into the base of the tongue about half an inch external to the middle line and drawn forwards, cutting well into the lingual tissues, the incision being repeated on the opposite side unless the glossitis be unilateral, as is the case in rare instances. This operation is usually followed by a free flow of serum and a moderate or small amount of blood, and in the course of a few hours the tongue has mostly returned to its normal size. If this be not the case, the incisions may be repeated and hot-water gargles freely used. This, however, is rarely called for. A large blister may also be applied across the hyoid region.

The general treatment will consist in smart saline purging, with a little antimonial wine in sthenic cases; in those due to sepsis, quinine in free doses will be indicated.

Sometimes glossitis is not so acute and diffused as in the cases just described, but is localised in one part of the body of the organ. This was well seen in a patient under my care some years ago. He said that he had had a severe chill from exposure some time before, and complained of a fulness in his tongue. On inspection of the latter, I found its right half slightly swollen, but otherwise presenting little signs of inflammation. On palpation, however, I detected fluctuation, and an incision at this spot gave exit to a drachm or two of pus. The cavity in this case shrank and disappeared in a few days. There was here no evidence of any cause except exposure, the man being healthy in every respect.

SYPHILITIC AFFECTIONS.

The *syphilitic diseases* of the tongue may perhaps be best considered in a special paragraph by themselves, holding as they do a somewhat uncertain position between the inflammations and the distinct new formations, at least as regards nomenclature.

Syphilis manifests itself in several ways in the tongue, and at any age. Hitherto but little notice has been taken of the congenital affections as they appear here; but there is reason to suppose that when looked for more carefully in those suffering from congenital syphilis, they will be found more frequently. In conversation with Mr. Bryant lately, he mentioned a case which had quite recently come under his notice, in which among other well-marked evidences of the inherited disease in an infant he had found a typical mucous papule on the tongue at birth. There can be little doubt that instances of gummatous nodules will also be found when more attention is given to the organ at birth, in these cases. This has been the history of the gummata in other parts in congenital syphilis, and there is no reason why the tongue should prove an exception.

Occasionally we meet with primary sores on the tongue; but though we must

remember the possibility of their occurrence, they are so rare that they need hardly count in any case of differential diagnosis. Their characters are similar to those presented by primary sores elsewhere, and need hardly detain us.

So far as we know at present, the earliest constitutional syphilitic lesion of the tongue is what is known as the mucous papule. This is met with, as a rule, within three months of the primary inoculation, and at the same time that mucous papules show themselves on other parts, such as the lips, vulvæ, and anus. On the tongue, the appearance produced by the lesion is the same as that seen on other mucous surfaces. The covering of the organ seems raised in usually oval or circular patches, which are of a pearly grey colour and covered with half-macerated epithelium which gives the mucus upon them a milky look. These patches may be met with on any part of the tongue or other part of the cavity of the mouth, but are less common in the former situation. They consist of an infiltration of the papillary layer of the tongue with small round cells whose pressure has disturbed the nutrition of the epithelial layers above. There is no pain or tenderness about them, and they give rise on the whole to little inconvenience. For this reason they may be overlooked by the patient, whose attention is probably engrossed by the appearance of the secondary rashes in the skin which develop about this time.

Except from the point of view of diagnosis, these syphilitic papules of the tongue are of little importance; they usually disappear readily under the influence of moderate doses of mercury, leaving no trace of their previous existence behind. Rarely, they are stubborn and require to be treated locally. Perhaps the best application in this case is a rather strong solution of Perchloride of Mercury used as a mouth wash; or the papules themselves may be rubbed over with nitrate of silver occasionally.

The next syphilitic lesion met with is one which usually appears at a somewhat later period in the constitutional disease—namely, at that stage which we are accustomed to speak of as the late secondary. It is characterised by a superficial diffused infiltration with the same round-celled deposit as in the last case, which has a tendency to break down in patches, leading to very shallow ulceration, irregular in outline and extent. Those portions not yet ulcerated are very slightly raised, are usually of a dark bluish-pink colour, and are quite smooth on the surface, although generally the latter may be a little rugged or fissured. The ulceration which takes place is usually very shallow, and may spread at one border while healing at another. It may, however, in a few cases form deeper cracks or fissures on the surface, but never usually to any great extent. After this form of syphilitic infiltration has been absorbed or removed by ulceration, which has healed, there is very often a remarkable staining of the recovered epithelium left behind. Over the area once affected there is now a bluish-white milky stain, of more or less deep tint, sometimes almost quite opaque, but usually allowing the colour of the deeper structures to shine through. After a time this will gradually disappear, owing probably to the altered epithelial cells being shed off in the natural course of things. This condition, when combined with the wrinkling or fissuring referred to above, is sometimes spoken of as psoriasis of the tongue, a term which has little to recommend it. It is sometimes confounded with leucoplakia or ichthyosis glossæ; but as we have seen that the latter disease is frequently, if not always, produced independently of syphilis (p. 565), the mistake ought for the future to be avoided, the true syphilitic affection being usually easily cured by ordinary anti-syphilitic treatment, the other being, if anything, only aggravated by it.

In the treatment of this secondary syphilitic condition local applications are rarely needed, and the constitutional remedies are usually quite sufficient for a cure. Occasionally, however, it is found that mouth washes appear to hasten the healing process. These may consist of strong solutions of Perchloride of Mercury or Bicarbonate of Soda, which I have observed to be of use in some cases. But in spite of all remedies the wrinkled and fissured condition of the organ will often remain long after all ulceration has healed.

The last syphilitic lesion of the tongue to which reference will be made here is that found usually late in the tertiary stage of the disease, in which the small-celled

deposit takes the form of a distinct circumscribed knot or nodule in one or other part of the organ. This knot or gumma, as it is called from the consistence of the material of which it is composed, is usually seated in the body of the tongue, contrasting thus with epithelioma, which, as will be shown later on (p. 593), commences generally on some part of the border, though not invariably. The granulation tissue of the gumma is seated in the muscular substance, and within the mass are found traces of the muscle fibres more or less altered. When such a gumma is fully developed and of any considerable size, it produces some discomfort to the patient on account of its bulk, but little or no pain as a rule if unbroken on the surface. It is felt as a soft elastic swelling, so elastic, indeed, as to give the impression to the finger of a fluid collection in many cases. The surface of the organ during the formative stage of gumma may or may not be altered. If the deposit approach the surface very nearly, the nutrition of the epithelial layers is usually somewhat disturbed, but beyond this little is noticed. But when degenerative changes take place in the mass the case is different, and the most superficial coverings of the nodule are involved in them. The changes met with in the gummatous material are the same here as elsewhere. It may either undergo resolution and absorption, or fibrous, calcareous, or caseous metamorphosis. When fibrous, a knot covered by a puckered depression may remain for a long time in the tongue, and the calcareous matter (which is rare, however, in this situation) may be mixed with the fibrous material. But when caseous degeneration takes place the softened material assumes the characters of a small cold abscess elsewhere. It remains perhaps quiescent for a longer or shorter period, and may even, under treatment, be absorbed, but in the majority of cases it works its way to the surface until eventually the coverings over it give way, and the broken-down tissue escapes into the mouth. A ragged depression is then left, with a sloughy floor composed of the softening gummatous material undergoing fatty degeneration. It is in this stage that some difficulty may be experienced in diagnosing the ulcer from epitheliomatous disease. The situation of the focus, however, helps us in the first place; then the fact that the base is sloughy, and does not present the induration always present in epithelioma; again, the edges are not hardened and nodular, but are usually somewhat undermined; finally, the glands in the floor of the mouth are not generally in any way affected in the syphilitic condition. The age of the patient may also help us, for if the ulcer be found under the age of thirty it is more likely to be syphilitic than cancerous, although, as will be shown later (p. 590), this general rule is not without exceptions.

The treatment for gumma of the tongue, so long as it has not broken down, will be that of syphilis generally. But when a deep ulcer has formed, it may be necessary to deal with the sore locally on account of the foulness of the discharge when once it has become contaminated by the ferments of the mouth. This is best done by filling the depression with powdered Iodoform after its surface has been first dried as carefully as possible. This dressing has the property of clinging very closely for days to any surface of the kind upon which it has been packed, and it will prevent all decomposition so long as a trace of it remains. If a remedy be not at hand, solutions of Chlorate of Potash or the permanganate may be used as mouth washes. But, though valuable, they do not come up to Iodoform, which is coming more and more into use as a dressing for all wounded surfaces about the mouth. As a rule these deposits or their results disappear readily under the ordinary anti-syphilitic treatment, but from time to time we meet with cases which are very stubborn, and resist all our efforts to remove them. Such cases should always be looked upon with suspicion, for it appears to be established that epithelioma may develop out of chronic syphilitic ulcers. There is nothing incredible in this, in view of the fact that prolonged irritation of any kind may be an exciting cause of cancer in one predisposed to the disease in other ways. In one of my own cases, that of a woman of twenty-six years of age (the earliest at which I have operated for epithelioma of the tongue), the cancerous growth appeared to develop at the seat of gumma. That the disease was epitheliomatous was unfortunately proved after excision of the organ, not only by microscopical examination, but also by the recurrence which took place in the glands of the neck and ultimately destroyed life.

TUMOURS OF THE TONGUE.

The most important group of diseases of the tongue now remains for consideration—namely, the tumours found in the organ, including those more strictly called neoplasms.

These all may be classed roughly into five groups: 1. The Vascular; 2. The Cystic; 3. The Lupoid and Tubercular; 4. The Connective-Tissue Group; 5. The Epithelial Group.

1. *The vascular tumours.*—Of the vascular tumours, we have already considered one—namely, lymphangioma, under the name macroglossia, usually given to the condition of the tongue produced by the change in the lymphatic tissue.

The next—namely, nævus—is perhaps the most common of all this group. This is usually first noticed shortly after birth, either confined to one portion of the tongue, or involving part of it and the floor of the mouth, lip, or cheek. Sometimes it is associated with some lymphangiectasis, in which case proneness to attacks of swelling and tenderness in the part is marked.

For a description of the minuter structure of nævus the reader is referred to the essay on TUMOURS. It need only be said here that nævi of the tongue present themselves either as small strawberry-like circumscribed eminences projecting from the surface of the organ, or as a more diffused vascular growth of the lingual substance proper.

The condition may be present to a considerable extent without producing any inconvenience, and may fail to increase in extent in many cases. But in other instances the tumour enlarges rapidly, and causes difficulties in eating and swallowing which call for interference. There are also risks of severe hæmorrhage from wound of the vascular tissue by the teeth during eating, or as the result of a blow or fall upon the chin. For these reasons, an operation is called for in many cases, and in the choice of the latter considerable room is given.

In the case of small more or less prominent growths which can be easily isolated, it was formerly the practice to pass a ligature round their base and strangulate them *en masse*. Here, however, as in the case of other tumours of the tongue, the use of the ligature is being abandoned for better methods. In such a case simple and free excision with the scissors is much preferable, the bleeding, if healthy tissue be cut into all round, being inconsiderable. But, if there be any particular cause to fear bleeding, the growth may be removed by the Paquelin's Cautery Knife, the tongue being drawn out of the mouth. This is an excellent mode of dealing with such tumours when small.

If the growth be large or diffused over a considerable area of the tongue, it is better to deal with it by excision, using the twisted wire *écraseur* (fig. 136) by preference, and working in thoroughly sound tissue. The use of the cautery here either for puncturing or excising the growth where a large surface is involved, is not desirable, in view of the irritating setor resulting from the sloughing action set up by the burn, the risks of which will be alluded to later on (p. 608), where the modes of using the *écraseur* will also be described.

Cirsoid aneurism of the lingual vessels has also been observed in one case at least. This is recorded by Sir J. Payrer,¹ who describes it carefully, as also the mode in which he treated it. Apart from the abstract pathological interest of this case, it is of clinical importance from the fact observed—namely, that the tumour was very like an ordinary ranula of large size, and might possibly be mistaken for such a condition.

2. *Cystic tumours.*—We turn next to the fluid or cystic tumours of the tongue.

Of these the first, and apparently rarest, is the *hydatid* which has, however, been found here as in other parts of the body. The treatment, too, will not differ from that adopted elsewhere for these parasitic cysts.

The next kind of cyst occasionally met with is one due to the dilatation of one

¹ *Clinical Surgery in India.*

or more of the *mucous follicles* of the tongue. These may occasionally attain considerable size, and may be misleadingly like colloid cancer of the organ, as in a case quoted by Weber¹ from Schuh's practice. They are very thin-walled and filled with a tough gelatinous mucus, and do not project much over the level of the tongue surface, though they may attain a considerable size. The treatment of such tumours will be the same as that adopted for ranula, a condition now to be described.

The swelling to which the term *ranula* is applied is usually found either in front of the under surface of the tongue close to the frænum or more generally at the side of the organ. It may be congenital or acquired; its appearance is very characteristic: it is smooth on the surface, of a dark pearly bluish-pink colour, and, even casually viewed, gives the idea of translucency; it is also distinctly fluctuating, the sensation being felt either with the finger in the mouth or, if the tumour be large, under the ramus of the jaw. The size is usually from that of a filbert to a walnut. These swellings are due to the distension of a part or the whole of one of the sublingual glands with normal mucus. This is not necessarily a consequence of blocking of the duct, which, as Sir W. Fergusson² has shown, may be found quite permeable to a probe, but may be a simple dilatation of the follicles of the gland. The contents are usually glairy, either quite clear and colourless, or else of a pale straw tint, and are enveloped in a very thin walled sac.

The treatment of these mucous collections, whether under or in the tongue, is not always a simple matter. If they are moderate in size, the better plan is to dissect them out as a whole. But, if larger, this would be rather a troublesome operation, if not actually dangerous from hæmorrhage. It is better, therefore, in the first place to try the effect of simple incision and drainage. It is done by making a cut with a sharp, curved bistoury, by transfixion through the most prominent part of the swelling. When this has been done, the sac very often drains, and shrinks completely without any trouble, and the disease is at an end. It very often happens, however, that this wound thus made heals too readily, and the fluid re-accumulates. This may even occur after repeated evacuations of the contents. In such a case the greater part of the external wall of the sac may be cut away with scissors, and the resulting hollow dressed with a piece of lint dipped in Tincture of Iodine. This is usually sufficient to obliterate these cavities, but even after this treatment the hole made may close over and mucus re-collect. If this take place, a V-shaped incision may be made in the external wall, and the triangular flap of the mucous membrane so formed may be turned into the sac, doubled on itself, and fixed thus with a single stitch. By this means a mucous surface is always opposed to the edges of the healing wound, and thus union is prevented, the sac shrinking. In the only case which I found it necessary to adopt this method I found it to answer very well. Sometimes it may be more desirable to excite inflammatory obliteration of the cyst by running a seton across it, and allowing it to remain there for some days.

But though ranula need not depend upon blockage of the duct of the gland, the latter is not unfrequently found to be obstructed by a hard concretion of phosphate of lime deposited from the secretion of the organ. Such a salivary calculus is easily felt upon the floor of the mouth as a hard stony knob covered by the mucous membrane of the latter. It can hardly be mistaken for any other tumour in this situation.

The treatment will consist in making an incision over the whole length of the foreign body, and in dislodging it with a small scoop, with which it can be levered out of its bed as a rule without much difficulty. In a few cases, if the calculus be rough, it may not be easy to dislodge it from the mucous tissues in which it is imbedded, and it may be necessary to break it up in situ rather than dissect or tear it out, which might produce considerable bleeding. Should the latter be smart, it may as a rule be controlled by the sucking of ice, and if not by this, by the application of lint dipped in Perchloride of Iron Tincture.

The last of the cysts of the tongue which it is necessary to notice are those containing *sebaceous matter*. These derivatives of the dermal structures may be found

¹ *Pfäa-Billroth's Handb. d. Chir.*, Einband vi. p. 329.

² *System of Surgery*, 5th ed. p. 513.

either in the mid line of the organ or at one side—in other words, in those two situations where embryonic clefts exist, and where infoldings of some of the elements of the cutaneous structures may occur. Such cysts are rare, and but few notices of special cases are to be found recorded in our literature. I can only refer to two instances of the occurrence of a sebaceous tumour of the tongue in my own practice. The first was seated in the middle line, between the genio-hyoglossi muscles, and was about the size of a walnut. It produced a considerable amount of difficulty in swallowing, and much discomfort. The patient, a woman of about five-and-thirty, was very anxious for its entire removal, which was accomplished without much trouble from the mouth. Having discovered the nature of the swelling by incision and the evacuation of the porridge-like contents, I seized the tough wall of the cyst with a strong forceps, and drawing on it firmly, was able to enucleate the whole in one piece by a dissection with a blunt director, although the cyst reached quite to the hyoid bone between the two muscles. The bleeding and pain were insignificant, and ceased almost immediately after the operation, the wound healing in a few days. On examination, the sac was found to have very thick walls composed of tough fibrous tissue, which was but loosely attached to the surrounding structures. The second is at the present moment under my care, and is the same in every essential particular, except that it is larger and does not produce any discomfort. The patient has not yet made up her mind to operation. Sir W. Fergusson¹ records another case of this same disease, which was remarkable for the great size which the cyst attained, and the trouble which was encountered in dealing with it. It was as large as the fist, and was prominent under the chin on one side as well as thrusting the tongue upwards, giving rise to much inconvenience. The sac of this tumour was only removed after extensive dissection, both from the mouth and side of the neck, during which the patient lost much blood. He made a good recovery, however, in a very short time. The only special point to be attended to in dealing with such sebaceous cysts is their entire and complete removal. Unless this is attended to, troublesome discharging fistulæ are the only result of opening them or attempting to cause their obliteration by inflammation.

3. *The lupoid and tubercular group.*—Lupus of the tongue is a disease of great rarity to judge by recorded cases. I have only been able to discover one such, in which the diagnosis could be said to be established beyond all reasonable doubt. The specimen was exhibited to the Pathological Society in 1875, by Mr. F. Clarke, who had shown the case to Sir James Paget, who had made the diagnosis. The patient died of exhaustion, from inability to swallow food, and the tongue on removal was found to be infiltrated with small round cells, in the way usually found in lupus. Probably the best treatment in a case of this kind would be excision of that part of the tongue in which the disease lay, if the latter were of moderate extent; if otherwise, in free scraping away of the lupoid tissue over the affected area.

Tubercular disease of the tongue, on the other hand, is probably not so rare as has hitherto been supposed, and attention has recently been drawn to several instances of the disease in its early stages and accurate descriptions given. One of the best essays on the subject is that of Nodopil,² who describes the affection very carefully, however one may be inclined to question some of his conclusions.

As the author has seen it, the disease has been present in the form of a small ulcer or ulcers on the dorsum of the tongue far back. These showed a sharp margin with a deeper red colour than the surrounding tissue, and a white shreddy base; they were irregularly circular and considerably excavated; their margin gave evidence of considerable deposit, without very marked induration; they were associated with similar disease of the soft palate, and other evidences of tuberculosis. I had no opportunity of examining the growth with the microscope. Nodopil has described the affection at an earlier stage, and has had an opportunity of examining the structure of the base of the ulcers microscopically. Here he has found the well-known miliary granulations of tubercle, either disseminated or aggregated, and break-

¹ *System of Surgery*, 5th ed. p. 514.

Archiv f. klin. Chir. Bd. xx.

ing down towards the surface of the ulcer. He suggests that it may be possible by a careful study of this affection of the tongue in the future to recognise its nature early enough to admit of its removal before extensive ulceration has taken place, and (inasmuch as the deposit may be primary) before possible generalisation of the tubercle have taken place from the original focus. Whether this be the correct treatment for this disease or not further experience must show. At present we rely rather upon scraping the base of the ulcer freely with a sharp spoon, and dressing it with Iodoform or Tincture of Iodine, than on the more radical operation of excising the portion of the tongue in which the ulcer lies.

It is a point of some little interest that the first of Regnoli's operations for excision of the whole tongue (see p. 602) was performed for what was described as a tubercular ulcer of the organ, in a girl of fifteen. It is more probable, however, from the description that the affection was more of the nature of lupus.

4. *The connective-tissue group.*—The next group of tumours of the tongue to be considered is that made up of the solid growths derived from the connective-tissue structures.

The first and by far the most frequent of these are the papillomata. These consist of the hypertrophied papillæ of the organ, and may be found on any part of its dorsum. They are most frequent, however, far back, and may be single or multiple. They are often congenital, but not always. They consist of a considerable increase of all tissues of the papillæ in about equal proportions in most cases. In some, however, the epithelial coverings are proportionately over-thick and are horny to some extent, as in a case alluded to by Weber.¹ Again one of the circumvallate papillæ may be hypertrophied, and exhibit in its interior glandular and enlarged nerve-elements as found by Billroth (*ibid*). Such growths may be either sessile or pedunculated, and may attain considerable size; one described by Dr. Huie weighing as much as an ounce on its removal by operation.²

When such tumours are found in children or young persons, they may be looked upon as quite benign; but when met with in mid life should always be regarded with a certain amount of suspicion, cases having been recorded in which they have developed into typical epithelioma. I have seen two or three such, in which, after excision, their true nature was seen to be epitheliomatous.

The treatment will consist in their removal either by the scissors, which is the simplest and best, or by the knife, cautery, or wire écraseur. When very small, free rubbing with nitrate of silver may suffice to lead to their being shed off rapidly.

Fatty tumours are also met with in the tongue, either embedded in its muscular substance or on its under surface, but rarely of any great size: they are very unusual, but cases are alluded to by Weber, and another is recorded in the 'Progrès Médical,' Dec. 11, 1880. Their removal is a matter of small difficulty, as they 'shell out' of the surrounding tissues readily, leaving a wound which soon heals.

Fibromata and fibro-cellular growths have been met with more frequently. These may be imbedded in the tongue, or may hang as pendulous masses from its surface, as in an interesting case recorded by Mr. Mason,³ where the tumours had attained the size of plums before relief was sought. In another case, alluded to by F. Clarke,⁴ one of these fibro-cellular tumours was removed from the tongue, on which it had been seated for twenty years, and was found to weigh a quarter of a pound. Many other less remarkable cases might also be cited of the same kind of growths.

Enchondromata have also been found here, and a remarkable case is described by Weber,⁵ in which he found such a growth of about the size of a walnut to contain masses of fat surrounded by and imbedded in cartilage. He mentions further that enchondroma has also been found here by Velpeau, but beyond these cases I am not able to find any record of this particular neoplasm having been observed in the tongue.

¹ *Pitha-Billroth's Handb. d. Chirurg.*, Einb. vi. p. 328.

³ *Trans. Path. Soc.* vols. xv. and xviii.

⁴ *Diseases of Tongue*, p. 313.

⁵ *Pitha-Billroth's Handb. d. Chir.* Einb. vi. p. 329.

Another very remarkable growth belonging to this group has also been observed on the tongue, at least in one case: this is keloid, which was associated with patches of the same disease in other parts of the body.¹

This leads us to consider the more truly sarcomatous growths in their relation to the tongue, and here it may be stated at once that as primary diseases they are almost unknown. I only know of one such case, in which, however, it might be questioned whether the condition of the tongue was altogether primary. The patient was under the care of my colleague Mr. Godlee, at University College Hospital, and when first seen had a somewhat pendulous growth upon the dorsum of the tongue. This was removed, but recurred before very long. There were also several growths of the same kind a little later on the skin of different parts of the body, so that the case on the whole was one of those rare forms of multiple sarcomata, to which attention has been lately drawn, but whose peculiarities require further study.

5. *The epithelial group.*—Turning now to the distinctly epithelial neoplasms observed here, we find that they are only two—scirrhus and epithelioma. The first of these has been met with, but is extremely rare. Thus, out of sixty-six cases of tumour of the tongue, occurring at University College Hospital (see p. 580), only one was distinctly of the nature of scirrhus. The latter form of disease, as it occurs here, requires no special notice, presenting no peculiarities either as to characters or treatment, which would be the same as that for epithelioma.

But by far the most important tumour of the tongue is unquestionably *epithelioma*, and this for several reasons.

* In the first place, of all the new growths developing in the organ, it is the most frequently met with, if we except syphilitic gummata, which may also be classed among the neoplasms. On this point I may first quote in evidence a careful collection of all the cases of tumour of the tongue, admitted into University College Hospital during the eleven years 1871-1881 inclusive, which I have tabulated from the hospital Case Books, greatly assisted by the valuable Reports furnished yearly by our Surgical Registrars. Cases presenting themselves as 'out-patients' have not been included in my list, which will be found below (p. 581).

Now, of the in-patient cases of tumour of the tongue alluded to, amounting in all to 66 (inclusive of 4 gummata of the tongue operated on by error or as suspicions), I find that there were only 10 not epitheliomatous, or 6 if we exclude the syphilitic deposits, these tumours were 2 Nævi, 1 Scirrhus, 1 Papilloma, 1 Sarcoma, 1 Lymphangioma. In out-patient practice the preponderance of gummata would of course be very great, but, leaving these out in this case, epithelioma stands far in advance of the other tumours of the tongue in frequency as demanding operation. Scirrhus, as already noticed, was only found once among 66 patients suffering from growths of the tongue, and the same was the case with sarcoma.

As further evidence on this point we may mention that, among 46 cases admitted for excision of the tongue into Billroth's Klinik within eight years (Oct. 1867 to Jan. 1876) and tabulated by von Winniwarter,² and 48 between the years 1877-80 tabulated by Woelfler,³ no mention is made of either of these last or other neoplasms, except gummata and tubercular nodules.

And, even admitting that there are many tumours of the tongue which would not necessitate a stay in hospital for their removal, my own observation of many thousands of out-patients confirms the conclusion as given above, derived from a study of the literature of the whole subject—namely, that epithelioma is the commonest neoplasm of the tongue, excepting syphilis, and perhaps papilloma.

Again, epithelioma of the tongue is important on account of its great frequency as a distinct affection in this country. On this point we are impeded of detailed statistics; but it is worth noting that in our hospital the ratio of cases of this disease admitted during the eleven years mentioned above* (amounting to 55,

¹ Sedgwick, *Trans. Path. Soc.* vol. xii. p. 284. Quoted by Clarke.

² *Beitr. z. Statist. d. Carcinom.* Stuttgart, 1878. ³ *Archiv f. klin. Chir.* 1881, p. 314.

excluding 4 gummata, 1 scirrhous operated on on doubtful diagnosis), stands at 4.5 per 1,000 of all the patients treated in the surgical wards during the same period, amounting to 12,199. And if, as would appear possible from an interesting suggestion made by Mr. Whitehead at our recent Medical Congress,¹ cancerous diseases be on the increase in this country, as shown by the Registrar-General's returns, we may expect that form which develops in the tongue to increase in the frequency of its occurrence too, seeing that it holds a prominent place in this group of affections. This relative frequency of cancer of the tongue as compared with other organs is a point of interest, and a glance at some of the recorded statistics of carcinoma will repay the trouble. Thus I find that 16.3 per cent. of all the cases of cancer, amounting to 343, including scirrhous, medullary, epithelial, and rodent, treated in our hospital within ten years were lingual, the breast standing at the top of the list with 36.7 per cent., the rectum coming next to the tongue with just 10 per cent. Von Winniwarter's² statistics of carcinoma, compiled from the hospital and private practice of Professor Billroth, give however a smaller percentage of tongue cancers to the total for all parts of the body—namely, 8.3, calculated from 543 cases: the breast standing at 32.4, and the rectum at only 4.3. But in von Winniwarter's tables carcinoma of parts of the face and lips swells the aggregate after the breast. Sir James Paget's statistics,³ on the other hand, like our own, show epithelioma of the tongue ranking among the cancers only next to the breast in frequency. Thus, on a total of 500 cases tabulated, there were 55.2 per cent. of breast cases, and 6 per cent. of epithelioma of the tongue. In Mr. Sibley's tables,⁴ compiled from the records of Middlesex Hospital for 1854–1856 inclusive, and including 520 cancers of all parts, the percentage of tongue cases is not so high, being only 2.6, while the breast stands at 36.5 of the whole. In this table, however, cancer of the uterus makes up 30.0 per cent. of the total, while it is not represented at all in Sir James Paget's or our own lists, and only to the extent of eight cases in von Winniwarter's.

While correcting the above 'copy' for the press, I have just now had an opportunity of hearing a most valuable paper on the statistics of ichthyosis glossæ, and of epithelioma of the tongue, taken from the records of the Middlesex Hospital for the years 1872–1881 inclusive, read at the Medical Society by Mr. Morris, who, with his usual courtesy, has permitted me the privilege of examining his tables and embodying his experience with the above. His figures include 501 cases of cancer of all parts, of which the breast makes up 51.4 per cent., the uterus 22.1, and the tongue 7.1.

If we combine these five tables, we have a very large number of cases of cancer from which to judge the relative frequency of that occurring in the tongue. The numbers stand thus, comparing lingual disease with that of the breast, to which it stands next if we exclude cancer of the uterus, which is not represented in Paget's or the author's tables, and only to the extent of eight cases in von Winniwarter's.

	Sibley: 520 cases (1853 to 1856) inclusive	Paget: 500 cases (1843 to 1861)	von Winniwarter: 543 cases (Oct 1867 to Jan. 1876)	Author: 343 cases (1871 to 1881)	Morris: 501 cases (1872 to 1881)	Average per- centage on total of 2,412 cases
Breast . . .	36.5	55.2	32.4	36.7	51.4	42.4
Tongue . . .	2.6	6.0	8.3	16.3	7.1	8.0

Looking at the figures so arranged one is struck with the great frequency of cancer of the tongue, equalling 8.0 per cent. on 2,412 cases of the same disease affecting a large number of different organs. Also, one cannot help speculating whether it is possible that the steady rise in the percentage indicated in the above tables, which are arranged chronologically, is anything more than accident. If the author's and Mr.

³ 'Statistics of Cancer,' by W. M. Baker, *Trans. Med.-Chir. Soc.* vol. xlv. p. 380.

⁴ 'Statistics of Cancer,' *ibid.* vol. xlii. p. 114.

Morris's lists be combined—as they fairly may be, being derived from the practice of two neighbouring hospitals during the same decennium—we have a tolerably regular series of epochs and a steady gradation from 2·6 to 11·5 per cent., a point of some little interest when we remember Mr. Whitehead's remarks suggested by the Registrar-General's returns. It may be, of course, that the possibility of cancer of the tongue being cured by operation is becoming better known than it was some twenty years ago, and that consequently many cases in the country which would then have been pronounced absolutely incurable and beyond reach are now advised to seek admission at our large metropolitan hospitals. The fact, however, is in any case suggestive.

In the next place, this tumour is most important on account of its malignancy in every sense of the word. It is not only exquisitely painful in a large proportion of cases in the advanced stage, from the necessary passage of food over the ulcerated surface, but even without this the pain is often agonising when the nerves of the tongue become involved in the cancerous change: it is then not limited to the mouth, but radiates up the side of the face and head, often to an almost maddening degree: intense pain in the ear, too, is often complained of. But the disease causes much suffering and even danger in another way—namely, by the intolerable fœtor it produces in the mouth, not only by its own degenerative changes and the decomposition of the resulting products, but also by the rotting of particles of food which collect in and around the sore and cannot be dislodged. This fœtor is not only insupportable to the patient himself, but also to those about him, rendering his life miserable. It may even prove dangerous by setting up inflammation in the lungs running rapidly to gangrene, from the inhalation of the putrid emanations night and day from the part. It is in this way that death has been caused in some cases where no operation was performed (*e.g.* instances by Moore,¹ and author's table No. 60).

Epithelioma is malignant above all in its rapid march towards a fatal termination. Of all forms of cancer there is none more swift in its development or more inevitably destructive to life within a short period of its appearance than this if left to itself.

It is usually fatal thus in one of four ways—either by generalisation and the marasmus so produced; or by infection of the cervical glands and parts around to the extent of pressing upon the œsophagus and thus preventing food from entering the stomach, as I have lately seen in a case under my own care for some time; or by the production of septic pneumonia from inhalation of foul matters generated about the growth; lastly, it may lead to a fatal issue by opening up one of the lingual vessels, or arteries of the neck, with profuse hæmorrhage, which may be directly dangerous from loss, or may produce suffocation from entrance of the blood into the larynx in large quantity.

Of the duration of life of those affected with the disease who are not operated on, from the time it first manifests itself until it kills, one can only speak approximately of course. It is, however, worth note that many independent observations on this point lead to almost the same conclusions, to which allusion will be made later on, when the operations for epithelioma have been considered (p. 606).

Bearing these points in regard to the great importance of the disease in mind, we have good reason to study it as closely as possible in every aspect of its natural history. This I have endeavoured to do personally, not only by close observation of a large number of cases clinically, but also by an examination of a great number of recorded cases, and first those which have been under notice in our own hospital, which I have tabulated in detail.

Moreover, in the hope of helping in the matter of the establishment of uniformity in clinical record of these cases, by which alone any reliable data for comparison of large numbers can be accumulated, I have so far modified the arrangement of my table as to assimilate it in structure as far as possible with von Winniwarter's and Woelfler's, which, though they differ from one another in a few minute details of form, constitute together the most complete record of the kind now extant. The subjoined list, then,

¹ *Trans. Med.-Chir. Soc.* vol. xlv. p. 47.

hardly differs in form from von Winniwarter's, except in being perhaps a little simpler, while its arrangement may be held to be somewhat fuller than Woelfler's. At all events, all three are so nearly alike structurally that they admit of being amalgamated one with the other for general conclusions or contrast, the fact of the whole group consisting of completed series constituting, however, their particular value. I have not considered it desirable to go beyond these extensive and completed series for material from which to draw numerical conclusions. Large numbers of cases which I have studied, amounting to hundreds, might have been added to them, collected here and there from the journals home and foreign, but such an addition would probably not have contributed to the accuracy of any deductions made, seeing that they were more or less isolated records, and might only be taken generally rather to represent the successful operations here or there. Such a collection, which is not of course without its own interest, will be found at the end of a recently published essay on Cancer of the Tongue now before me, by Dr. Berg of Stockholm.¹ No doubt in a few years we shall have a much larger number of complete and accurately recorded series; in the meantime it is safer to be guided by collections of the character of those referred to specially in the text.

In the following table (pp. 580-589), which has been made as full and accurate as possible, I have arranged all the cases treated for cancer of the tongue in the wards of University College Hospital between January 1, 1871, and January 1, 1882, whether operated on or unoperated on, exclusive of out patients.

Ætiology.—The first point which suggests itself from a study of the table is whether locality has anything to say to the production of epithelioma. This is a very difficult question to decide, for want of extensive and accurate statistics. And yet here and there we find fragments of evidence which appear to answer in the affirmative. Thus a very considerable proportion of cases at our hospital have come from Wales; and within the last month or two we have had three such—two not only Welshmen, but also fellow-workmen in the same foundry, and with identically the same local tongue cancer. All this of course may be only a coincidence, or perhaps due to the fact that we have had, and continue to have, many Welsh students at University College Hospital, who on their return home would naturally refer any cases of the kind to their own hospital. But, on the other hand, we do not notice any remarkable number of breast cancers coming from Wales, as might be expected if this last were the only reason. There remains, therefore, the suspicion that locality may have something to do with the affection, especially as we are told that epithelioma of the lip is also common in Wales, which, to judge by experience at our hospital, is not the case in this neighbourhood. This suspicion is strengthened when we come to examine other series of cases where any data exist bearing on this point. Thus Woelfler notices the very large proportion of tongue cancers which seek relief in Professor Billroth's Klinik coming from the immediate neighbourhood of Vienna and Lower Austria; while breast cases, for instance, come less from here and more from localities at a greater distance. One might be disposed, perhaps, to refer this prevalence of tongue disease in certain places rather to the hard living of closely populated parts or great towns—i.e. the drinking, and especially smoking habits. In reference to the latter, however, we are told (von Winniwarter, *loc. cit.*) that in parts of the East, where smoking is, if anything, more habitual than in Europe, cancer of the tongue is but little known; and, again, that among 100 cases of lip and tongue cancer collected by Hertaux in Finistère, where all the women smoke short pipes, there was not a single female. The whole question, however, requires much more extensive and careful study than has been possible hitherto, before anything more than mere suggestion can be hazarded in one direction or another in regard to it. I have thought it, however, of sufficient interest to claim a passing notice here.

In the next place, the period of life at which epithelioma manifests itself claims attention. On this point the following tables, arranged by several observers from different material and at different times, may be allowed to speak without much further comment. The extremes of age at which the disease has been observed are

¹ *Studier Öfver Tunghkräftan.* Af J. Berg. Stockholm, 1881.

No. Sex. Age. About. Date of admission.	First evidence of disease, when and where noticed.	Present state of primary disease. Pain.	Any glands enlarged, and where.	Etiological data. 1 Heredity. 2 Smoking. 3 Syphilis. 4 Leucoplakia. 5 Irritation & Induration.	Date and mode of operation.	Course and after treatment.	Immediate result.	Delayed cause of death.	Ultimate result.	Remarks.
No. 1. M. 44. Surrey. Aug. 31, 1871.	Six months ago; a small lump on right side of T., growing rapidly about two months later.	A large ulcer extends from tip almost to base on right side, nearly reaching the mid line. Great pain.	Yes, form of large swelling on right side of angle of jaw.	No heredity. Smoking moderate. Syphilis not mentioned. Local irritation not mentioned.	None attempted.					Patient never suffered from any illness except inflammation of lungs and gonorrhoea.
No. 2. M. 45. London. April 3, 1871.	Ten years ago began to complain of T. Right months ago began to ulcerate on right side.	Large ulcer reaches from near the base to the tip. A squarish nodule, also ulcerated, seen in tip, surrounded by thick white epithelium (?) Leucoplakia.	No.	No heredity. Smoking clay pipe. Syphilis local. No local irritation.	Inclined.					This patient probably had leucoplakia for years.
No. 3. M. 44. Bolton-le-Ware. March 17, 1873.	Three and a quarter months ago small, painful, painful, growing to present size.	Hard oval lump, size of shilling. No pain now. Position not mentioned.		No heredity. Smoking not mentioned. Syphilis in gums. Local irritation sharp teeth assigned as cause.	Declined.					Never had anything the matter with T. until date men tioned.
No. 4. M. 46. London. Jan. 23, 1873.	Three months ago a large wart driven into the tongue by a blow, the wound grew to present state.	Round, deep, hard ulcer, size of a shilling on left side of dorsum and lateral surface.	Yes, severe angle of jaw.	No heredity. Smoking not mentioned. Syphilis in ventral wound of tongue from pipe at base.	In 29 Division of T. cut with scissor, and left half removed with cautery at base.	Profuse secretion of saliva and mucous. Cough Much better treated by Condy's fluid. Swelling of left side of face slowly removed at Alcega in ear lobes and timp fossa.	R		Recurrence in glands soon after operation.	There was no hemorrhage during the operation from T., but free from incision in cheek.
No. 5. M. 52. Surrey. Feb. 12, 1873.	Two months ago a small tubercle on right side, rapidly growing.	Large ulcer from near tip to pillar of fauces deep and hard, nearly reaches mid line. Not painful.	Yes, one beneath jaw.	No heredity. Smoking moderate. Syphilis not mentioned. Grading of sharp teeth.	Feb. 19, Galt extra through the month considerable hemorrhage at the time. Organ removed at base.	Brachitis set in on 6th day, followed by pneumonia and pleurisy.	D	Died Feb. 26 of lung complications, i.e., bronchitis, pneumonia, and gangrene of lung.		The kidneys showed no signs of pyemia. nor did the lung appear to be diseased due to the latter disease.
No. 6. M. 61. Gloucestershire. April 12, 1873.	Seven months ago a sore spot on left border of T.	Large deep ulcer on dorsum, from three quarters of an inch of tip to papilla.	Yes one.	Heredity not mentioned. Smoking excessive.	April 16, Galt, extra near from the month. Left half removed by two incisions.	Hemorrhage on 7th day, otherwise covered good.	R			Pipe always smoked on opposite side to that affected.

[illegible]

No. of case.	First evidence of disease when and where noticed.	Present state of primary lesions.	Any kind of ulcer.	Hereditary syphilis.	Date and kind of operation.	Course and after treatment.	Ultimate result.	Remarks.
No. 16 M. 37. London. April 26, 1873.	First evidence of disease when and where noticed.	Present state of primary lesions.	Any kind of ulcer.	Hereditary syphilis.	Date and kind of operation.	Course and after treatment.	Ultimate result.	Remarks.
No. 17 M. 41. London. Nov 19, 1875	First evidence of disease when and where noticed.	Present state of primary lesions.	Any kind of ulcer.	Hereditary syphilis.	Date and kind of operation.	Course and after treatment.	Ultimate result.	Remarks.
No. 18 M. 42. London. July 29, 1875	First evidence of disease when and where noticed.	Present state of primary lesions.	Any kind of ulcer.	Hereditary syphilis.	Date and kind of operation.	Course and after treatment.	Ultimate result.	Remarks.
No. 19 M. 43. London. Sept. 21, 1875	First evidence of disease when and where noticed.	Present state of primary lesions.	Any kind of ulcer.	Hereditary syphilis.	Date and kind of operation.	Course and after treatment.	Ultimate result.	Remarks.

No. Sex. Age. Abode. Date of admission	First evidence of disease, when and where noticed	Present state of primary disease. Pain	Any glands enlarged, and where	Etiological data. 1. Heredity. 2. Smoking. 3. Syphilis. 4. Local irritation. 5. Leucoplakia. 6. Indigestion &c.	Date and mode of operation	Course and after treatment	Immediate result	Date and cause of death	Ultimate result	Remarks
No. 27. M. 26. London. Feb. 20, 1877.	Seven years ago a lump, size of hazelnut, removed from T.; ulcers since; twelve months ago ulcer on right side.	Deep irregular fissure in right side of dorsum with ulcerated border. T. is fixed in mouth; also a round swelling in left side of T. ramus. Pain and salivation.	Yes, one at each angle of jaw with others along ramus.	No heredity. Smoking not mentioned. Had syphilis—feet said to have irritated the T.	Feb. 21. Gaily, cancer to sever sublingual tissues and body of T.; scissors to take away some parts of growth left behind in stump.	Cough, troublesome on second day; bleeding on fifth day stopped by actual cautery.	—	?	Returned ten days after discharge with recurrence in floor of mouth and glands.	Left hospital with signs of recurrence.
No. 28. M. (?) Hagerston. Aug. 16, 1877.	Two years ago sore-ness on right side.	Extensive ulcer on right side from tip to root, and running on to floor, where T. is fixed.	Yes, one very large and hard.	No heredity. Smoking not mentioned. Syphilis mentioned.	None attempted. Disease too far advanced.	—	—	?	?	Pain and salivation great, much emaciation.
No. 29. M. 46. London. May 3, 1877.	Fourteen years ago a small pimple; this began to spread seven years ago.	Ulcer on right side.	Yes, very large at angle of jaw and present at present mastoid.	No heredity. Smoking not mentioned. Had great drinker.	None attempted. Disease too far advanced.	—	—	?	?	Pain very severe.
No. 30. M. 50. Gloucestershire. Aug. 27, 1877.	Seven months: 'a few small pimples noticed before.'	Large irregular cavity in mid two-thirds of left sternum; also ulceration on right border. T. fixed.	Yes, many at angle of jaw and above clavicle.	Heredity not mentioned. Smoking not mentioned. Had syphilis.	None attempted. Disease too far advanced.	—	—	?	?	Pain and fever very great.
No. 31. F. 49. Berkshire. March 16, 1877.	Twelve months ago sharp tooth caused an ulcer to form.	Ant. three-quarters of T., enlarged, thick, hard.	Yes, at angle of jaw and above clavicle.	No heredity. Smoking not mentioned. No syphilis. Scraping of T. by sharp tooth.	None attempted. Disease too far advanced.	—	—	?	?	—
No. 32. M. 66. Jan. 6, 1877.	Six months ago cut T. on right side with sharp tooth; ulcer formed, did not heal.	Hard, flat oval ulcer. Size of shilling, on right side of dorsum.	Yes, one in neck.	No heredity. Smoking not mentioned. No syphilis.	Jan. 10. Gaily, cancer for right half portion left behind, scissors when the ling. art. was cut, and had to be ligated.	On 12th a cough began and lasted till death.	D.	Double bronchio-pneumonia with grey hepatisation in right base.	—	The original cut on T. was freely cauterised two to three times a week!

No. 33. M. 40. Surrey. Dec. 19, 1877.	Six months ago pain in T., sore for three months.	Post. two-thirds of left half ulcerated; bottom of ulcer extended to right half and to hyoid bone.	Yes, at angle of jaw on right and left.	No heredity. Smokes to excess. Syphilis not stated. Scraped T. with Clay pipe.	No heredity. Smokes to excess. Syphilis not stated. Scraped T. with Clay pipe.	April 14. Wire excised through a modified Regnol incision; ant. third of T. removed.	Good recovery.	—	?	Pain severe.
No. 34. M. 53. Lincolnshire. April 10, 1877.	Five months ago a hard nodule in tip; grew painful and was removed eleven weeks ago.	Tip of T. fixed to floor, by growth reaching first molar.	Yes, at angle of jaw on right and left.	No heredity. Smokes to excess. Syphilis not stated. Scraped T. with Clay pipe.	No heredity. Smokes to excess. Syphilis not stated. Scraped T. with Clay pipe.	April 14. Wire excised through a modified Regnol incision; ant. third of T. removed.	Good recovery.	R.	—	The écarosseur cut through T. in thirty-seven minutes; only a little oozing of blood.
No. 35. M. 42. Buckinghamshire. March 13, 1878.	Five months ago, sore on T.	Hollow ulcer, size of shilling, on right side of under surface at first and second molar tooth, later a good deal of continuous pain.	None when admitted.	Heredity, yes. Smokes to excess. Syphilis doubtful. Holds pipe between buccal and first molar teeth.	Heredity, yes. Smokes to excess. Syphilis doubtful. Holds pipe between buccal and first molar teeth.	March 15. Portion of T. containing the ulcer removed with scissors; free bleeding stopped with actual cautery.	Good recovery; left wound nearly healed.	R.	?	The growth was plainly not removed by the second operation, but patient was much relieved for a little. Third operation on July 4, as before, the pain being intense since last. Oct. 10, secondary growth; wound divided in usual way. Patient discharged 14th, considerably relieved.
No. 36. M. 65. London. March 13, 1878.	Not stated.	Whole T. indurated, ulcerated on dorsum chiefly on left side; very little pain.	Yes, one under ramus of jaw.	Heredity not mentioned. Smoking not mentioned. Syphilis not mentioned.	Heredity not mentioned. Smoking not mentioned. Syphilis not mentioned.	March 20. Wire excised from mouth round base of T.; had to be re-applied for fragments of growth left behind. Nose and attachment of uvula were divided with scissors.	March 21. Com- plained of difficult breathing, which became intense within a few hours; on 25th became livid and laryngitis was performed in extremis.	D.	Died March 25, double pneumonia. All the growth had not been removed.	—
No. 37. M. 64. Wales. May 22, 1878.	Twelve months ago a small crack on left border, which increased slowly.	Ulcer, size of sixpence, on post-third of dorsum, on left side; hard, slightly painful.	None.	Heredity probable; one sister died, cancer of breast. Never smoked. No syphilis. T. rubs against false teeth.	Heredity probable; one sister died, cancer of breast. Never smoked. No syphilis. T. rubs against false teeth.	May 23. Growth removed, piece removed by cutting; bleeding stopped with Paquin's cautery.	Good recovery; a little bleeding (27th). Mouth washed with Glycerine fluid; left hospital June 4.	R.	—	Patient relieved by operation, but probably only temporarily.
No. 38. M. 61. Wales. March 16, 1878.	Not stated.	Whole right half of T. destroyed, floor healthy.	None.	Heredity not mentioned. Smoking not mentioned. Syphilis not mentioned.	Heredity not mentioned. Smoking not mentioned. Syphilis not mentioned.	March 27. Wire excised from mouth, the attachments of T. having been cut with scissors.	Good recovery; mouth dressed with Glyc. c. Acid. Carbol.	R.	—	Recurrence probable in stump before leaving hospital.

No. 44. M. 44. London. Oct. 6, 1879.	Six months ago slight sore, growing rapidly worse.	Itched, ulcer on left side from about one inch from tip to pillar of fauces, in duration of left half of T. only.	Yes, at left angle of jaw.	No heredity. Smoking not mentioned. Syphilis (?) syphilitic ulcer. Leucopha-kia buccalis.	For Preliminary laryngotomy wire encased from month round base of T.	Recovery at whole, though there was much swelling of the glands for a time, and pain.	—	The line of removal did not quite clear the growth.
No. 45. M. 31. London. Sept. 26, 1879.	Three years ago cut T. with cankered, ulcer grew fast.	Whole T. quite gone; flaps of epithelium with epitheliomatous growth.	Yes, under jaw, front of sternomastoid.	No heredity. Smoking not mentioned. Syphilis not mentioned. Scraping of sharp tooth.	None attempted. Ulcers too far advanced.	—	?	The growth involved the chin and had begun to break through before leaving hospital.
No. 46. M. 43. Kent. Dec. 4, 1879.	Three months ago swelling of T. noticed, attributed to bites during epileptic fits; constant pain.	Raised, hard ulcer on right side one inch and a half from tip, half-inch from mid. line, extends to pillar of fauces; great induration and tenderness.	None.	No heredity. Smoking not mentioned. No syphilis. Frequent bites of T.	Dec. 9. Preliminary tracheotomy; wire encased by a paravertebral incision. Right half removed.	Month drained by silver tube in floor with rubber tube attached. Overdose of morphia third day, requiring artificial respiration and stimulants; not cured. After this went on well but was troublesome; finally developed pneumonia.	Dec. 2. 1880. Pyæmia with abscesses over spleen and infarcts in kidneys; not diseased.	No trace of secondary growths found, P.M.
No. 47. M. 28. Bournemouth. Nov. 5, 1880.	Three months ago hard sore on left side from chaffing of sharp tooth; growing steadily.	Irrregular shallow ulcer made up of several smaller sores on left side of floor, floor free; no pain; much salivation.	Yes, under ramus of jaw.	No heredity. Smoking to excess. No syphilis. Irritation of a sharp tooth.	November 5. Wire encasement from the mouth; a piece left behind was first removed. Left half removed.	Recovery; wound washed with Condy's fluid.	Died Jan. 7, 1881, of generalisation of growth and carcinoma.	Recurrence in stump suspicious before leaving; glands enlarging more.
No. 48. M. 56. London. Jan. 15, 1880.	Three and a half months ago prickling pain in left border, ulcer a month later.	Deep narrow ulcer on upper surface on left side from frænum, one inch backwards, much induration; shortening pain.	Yes, several along sternomastoid and at angle of jaw.	No heredity. Smoking not mentioned. No syphilis. Occasional sores under T., probably dyspeptic.	None attempted; disease too far advanced. Discharged Jan. 17.	Very good recovery; suspicious induration about stump on leaving hospital.	Died Feb. 21, 1881, of carcinoma; metastases of new growth in internal organs.	Re-admitted two days before death.
No. 49. M. Dover. Sept. 10, 1880.	Seven months ago, after a bad sore throat, pimple appeared on right side far back; four times cankered.	Small ulcer on right dorsum; induration of almost whole of right side; T. fixed; pain and salivation bad.	Yes, many under ramus of jaw.	No heredity. Smoking not mentioned. Had syphilis.	Sept. 15. T. split on half dissected free with scissors and removed with wire encasement at base; profuse bleeding requiring laryngotomy.	Very good recovery; suspicious induration about stump on leaving hospital.	—	Recurrence probable before leaving hospital. Glands then still enlarged.

No. of case.	First evidence of disease, when and where noticed	Present state of primary disease. Pain	Any enlarged glands, enlarged, and where	Etiological data. 1. Heredity. 2. Smoking. 3. Syphilis. 4. Local irritation. 5. Leucoplakia. 6. Indigestion, &c	Date and mode of operation	Course and after treatment	Immediate result	Date of death	Ultimate result	Remarks
No. 50. M. Abdo. Date of admission	Nine months ago a small vesicle on right side which soon became a small ulcer.	Ragged ulcer from pillar of fauces to near tip on right side; but little pain; (?) leucoplakia.	Yes, one enlarged at hyoid bone slightly felt.	No heredity. Smoking to excess. No syphilis. Sharp end to pulp stem.	March 17. T. split, diseased half freed with scissors then removed with wire crescent from month; growth not completely removed.	Very good recovery; no pain. On April 2 a small recurrent nodule was cut away with scissors from stump.	R.	?	Recurrence in pillar of fauces and stump. Growth same character as before. Glands enlarged.	A second operation was done for recurrence on July 10: growth removed in stump by ligature. Glands same character; growth still enlarged and grew later in stump.
No. 51. M. 49. London. April 20, 1880.	Two months ago a small ulcer on left border, growing fast in all directions.	Large ragged ulcer on left side and near; not much pain.	Not stated.	Heredity not mentioned. Smoking to excess; clay pipe. Had syphilis (look by trade-catalogue).	None attempted, as patient was suffering from well-marked diabetes mellitus.	—	—	?	?	There was profuse hemorrhage from the ulcer while in hospital and on other occasions.
No. 52. M. 53. London. Dec. 21, 1879.	Seven months ago small lump on right side posteriorly, growing fast.	Large oval ulcer on right side of dorsum and touching pillar of fauces. No pain.	Yes, several under jaw and in neck.	No data given except chill and sore throat twelve months ago.	None attempted, the patient being in advanced pithitis.	Slowly sank.	—	Died April 26, 1880, of phthisis and cancer mammae combined.	—	—
No. 53. F. 78. Dec. 17, 1880.	Twelve months ago a sore on left side of tip.	Whole tip and ant. part ulcerated away.	Yes, several under jaw behind and in front of sternomastoid.	No data given.	None attempted, disease too far advanced. Discharged Dec. 15, 1880.	—	—	?	?	—
No. 54. M. 20. London. Sept. 26, 1880.	Nine months ago small ulcer on left side, probably syphilitic, which grew into present form.	Ragged sore quarter of an inch deep on left border, both large, with much induration around.	Yes, two at angle of jaw.	Heredity not mentioned. Smoking not mentioned. Had syphilis.	None; patient left by his own desire on Dec. 29.	Severe bleeding just before and during stay in hospital.	—	?	?	This looks like one of those cases where a syphilitic ulcer develops into epithelioma.
No. 55. M. 48. Surrey. Oct. 25, 1881.	Not mentioned.	Ulcer at left border from pillars of fauces forward. T. fixed; floor much indurated; jaws fixed; tonsil hard. Pain very severe.	Yes, many at angle of jaw.	No heredity. Smoking not mentioned. Syphilis not mentioned.	Oct. 26. T. split with scalpel. Wires sutured over left half which left growth behind. reapplied for remainder, part of which was cut away with scissors.	Had cough for a day or two, but made otherwise a good recovery.	R.	—	Recurrence in stump removed before leaving hospital.	The growth was plainly only removed. The amount of excision of the jaw was very remarkable in this case.

No. 56. M. 60. London. Oct. 5, 1881.	Nine months ago a small hard spot on centre of left half, which grew slowly to present condition.	Yes, one inch, and a half, reaching from border of T., a small ulcer on inner surface on left side. Pain moderate.	Yes, under ramus of jaw on both sides.	No heredity. Smoking not mentioned. Had syphilis.	Attachment with scar placed in greater part of organ removed. Left lingual art. ligated and was spayed and was healed.	Admitted charged Oct. 15; glands still enlarged, no obvious recurrence in stump.	Nov. 2, 1881. Glands re-charge, and extra glands, were enlarged. The floor of mouth was healed but hard.	Patient was plainly thinner on discharge, and extra glands, were enlarged. The floor of mouth was healed but hard.
No. 57. M. 60. London. Oct. 17, 1881.	Two years ago a small sore spot on middle of dorsum, growing to present size.	Long ragged ulcer along left border, from tip to base almost, floor of mouth is healthy; rather painful.	Yes, under ramus and at angle of carotid triangle on both sides.	No heredity. Smoking habitually. Syphilis not mentioned.	Oct. 19, T. cleared with scissors, were cauterized over base of blood on division. Paquet's cautery applied; bleeding checked.	A little bleeding on 24th; bronchitis.	—	—
No. 58. M. 62. Hertfordshire. April 4, 1881.	Four months ago blistered tongue and mouth; later a small ulcer seen where cancer now is; grew steadily.	Shallow ulcer 4 x 1 in. of right side and of mid-line and of floor; hard, well circumscribed, no pain or much salivation.	None.	Heredity (?). Smoking not mentioned. No syphilis. No local irritation.	May 4. Incision through carotid artery, an inch long over lymph; wire cauterized, introduced through this and round base of right half, being passed through centre of T. Free bleeding; tracheotomy performed. Then spit with knife and operation on glottis.	Sponges left in trachea first day. Tracheal wound left open for breathing for about ten days, then slowly closed. Had a good deal of cough, but made a good recovery, being out of bed on April 11, and changed June 2.	Recurrence in carotid glands soon after leaving hospital.	Patient returned to have glands removed, but on making an incision down on them they were found to be too firmly seated for safe enucleation.
No. 59. M. 49. Berkshire. March 29, 1881.	Three months ago small purple on left side of tip; others underneath.	Large, shallow, hard, irregular ulcer over whole left half. T. bound down to floor; pain on stant.	Yes, many under left ramus and on side of neck.	No heredity. Smoking habitually. Syphilis doubtful. Clay pipe; wire tongue often.	None attempted; dissection too far advanced.	—	?	Cachexia well marked.
No. 60. M. 44. London. August 29, 1881.	Eight months ago sore on right side of back of T.; grew steadily; T. became fixed.	Ulcer on right border which fixed to floor and much indurated; excess of saliva. Pain sharp.	Yes, on both sides under jaw, most on right.	No heredity. Smoking habitually. No syphilis. Clay pipe on right side ten years; no mouth-piece.	None; dissection too far advanced.	Died Dec. 1, 1881, of starvation, the swollen glands having for some time prevented swallowing. Sepsis pneumonia found with fatal abscess in left lung.	—	Patient had been seized with violent dyspnea on Sept. 17, which lasted some days.

DISEASES OF THE TONGUE.

shown to be 26 (one of the author's cases, No. 43, which died afterwards of recurrence), and over 80, and between these the cases arrange themselves as below :—

	20-30	30-40	40-50	50-60	60-70	70-80	80-90	Total
Clarke	1	6	12	11	7	2	—	39
Von Winniwarter, from Billroth's Klinik	2	8	13	17	6	—	—	46
Author, from University College Hospital	1	6	21	17	12	3	—	60
Woelfler, from Billroth's Klinik	—	6	13	19	9	1	—	48
Rose, of Zürich	—	1	2	1	3	—	—	7
Paget	3	5	8	8	3	2	1	30
Morris, from Middlesex Hospital	1	3	19	21	12	4	—	60
	8	35	88	94	52	12	1	290

The bulk of the cases, it will be seen, lie between the ages 40 and 60, or on closer examination, between 45 and 55.

The next question is, the relative frequency of epithelioma of the tongue in the two sexes; and here the same tables may be combined again, giving the following results :—

	Males	Females	Total
Clarke	28	11	39
Von Winniwarter, from Billroth's Klinik	43	3	46
Author, from University College Hospital	55	5	60
Rose	6	1	7
Paget	19	11	30
Woelfler, from Billroth's Klinik	48	—	48
Morris, from Middlesex Hospital	48	13	61
	247	46	293

Thus, on a total of nearly three hundred carefully recorded cases, we only find 15·6 per cent. of females to 84·3 per cent. of males. It is worth noting, however, that in the Serafimer Hospital in Stockholm, out of 21 cases of cancer of the tongue tabulated by Berg,¹ there were 11 females affected.

The reason for this great frequency of epithelioma of the tongue among males, as compared with females, is extremely difficult to account for satisfactorily, but will be apparent to some small extent, perhaps, when we have studied the ætiology of the disease more in detail. But it should not be forgotten that, when disease of the breast and uterus are excluded, cancer generally is much more frequent in males than in females. Thus, combining Paget's, Sibley's, and von Winniwarter's tables of cancer in all parts, we have a total of 1,568 cases, of which 1,006 were females and 562 males; but, subtracting 794 cancers of the breast and uterus from these, there remain only 212 females affected, against 562 males.

In considering the pathological and clinical materials now at our disposal, there appears to be little room for doubt that epithelioma of the tongue is in some way connected with local chronic irritation of one form or another. And that this may produce the disease without any hereditary cancerous taint appears equally clear. Thus von Winniwarter states that 'inheritance is excluded in almost all his cases.' In my own collection the evidence on this question is as follows—family taint is distinctly negatived in 20 cases, is simply negatived in 22, is only positive in 1, is doubtful in 4, and no statement on the point is made in the rest. These figures speak for themselves. 'The conclusions they point to are strengthened by the results of an analysis of Mr. Morris's collection of 61 cases. Of 29 of these, in which a note is furnished on this point, cancerous taint is negatived in 22, is doubtful in

¹ *Studier Öfver Tungkraftan*. Stockholm, 1881, p. 4.

5, and is only distinct in 2. In the face of such facts it would appear as though the occurrence of cancer in the families of those who have the disease in the tongue was little more than a coincidence.

As to the actual forms of local irritation which appear to give rise to the disease, they are many, as might be expected when we consider the variety of substances taken into the mouth, and the injuries to which the tongue is liable. Among those most commonly met with are such as are due to bites repeated at one spot or other, the chafing of a decayed or false tooth, or one constantly covered with tartar, the rubbing of the rough end of a pipe stem, &c.; then the habitual use of over stimulating foods, fluid or solid, such as ardent spirits, spices, onions, garlic, or, the chewing of tobacco. Again, burns on the tongue are dangerous in the same way—a very striking illustration of this being given by von Winniwarter (*loc. cit.* p. 209). Here the origin of the disease was a small ulcer, the result of a burn made by the application of the lighted end of a cigar to the tongue. But, above all, that irritation due to habitual and excessive smoking is dangerous, not only on account of the constant stream of hot vapour upon one part of the tongue, but also from the acrid products of dry distillation present in tobacco smoke. Of these, carbonate and acetate of ammonia, carbolic and acetic acids, which have been shown by Professor Ludwig,¹ after very careful analysis, to be present in relatively large quantity, are probably particularly injurious. The prolonged action of these upon the tongue is such as to give rise in certain persons to a species of chronic superficial glossitis, which has already been specially described under the name of leucoplakia lingualis (p. 562), or ichthyosis glossæ. This condition may last for years without producing any ill effect, but not unfrequently, on the addition of some slight external irritant, will commence to undergo epitheliomatous change. Thus the latter has been known to start at a spot of the tongue from which a patient had been in the habit of peeling or shaving off the thickened leucoplakial epithelium due to the chronic glossitis caused as above (von Winniwarter, Case 9, Table 13). In other cases, a bite or other injury to the 'smoker's tongue' has been the starting-point of the new growth. But many cases are recorded in which epithelioma has commenced in the smoker's or leucoplakial tongue, without any known injury in addition. How far chronic gastric irritation may tend to produce irritation of the superficial layers of the tongue to such an extent to give rise to a condition resembling, if not identical with, that produced by smoking is still uncertain. There seems good reason to suppose, however, from the evidence of some recorded cases (Möller²), that this cause, too, may operate in the same direction. But that smoking is one of the most fertile sources of epithelioma of the tongue seems clear not only from its manifest ætiological relation to leucoplakia, which so frequently runs on to cancer; but also from the fact that many of those who are affected with the latter, without any previous leucoplakia, have been excessive smokers, and attribute the commencement of their disease to the soreness produced by this. Among the 60 cases I have tabulated it will be seen that 29 are reported as smokers, and of these that 10 indulged in the habit to excess, and 18 moderately or habitually; 6 did not smoke at all. No statement on this point is made with regard to the rest. In the Middlesex Hospital table, notes are not forthcoming on this point in a sufficient number of cases to be taken in evidence. Still, many of the patients are reported as smokers, excessive or moderate. Of course it will not be argued that every man who smokes runs a risk of developing lingual cancer; for of the thousands who do so, probably only a small proportion suffer from this disease. But that many individuals would never have had the disease if they had not indulged in the habit to excess appears very probable indeed. It may be that here we have some of the reasons, at all events, why men are so much more liable to cancer of the tongue than women, as shown above—namely, that the latter do not so commonly smoke, chew tobacco, or drink ardent spirits, or generally use the more stimulating forms of food.* On the other hand, it is stated by von Winniwarter that in the East, and in those places where women also indulge in this habit of smoking, epithelioma of the tongue is as rare among them as among ourselves. It appears possible, however, that this

¹ *Archiv f. klin. Chir.* Bd. xx. p. 363.

² *Deutsche Klinik*, 1861, No. 26, p. 273.

disease may be more frequent in the weaker sex in this country than it appears to be in Germany. At least this would appear from a glance at the above table (p. 590) where an addition of the figures in the four English collections gives, out of 190 cases, 150 males to 40 females, or 79.0 per cent. to 20.9 respectively; while the three German series combined give 97 males to 6 females in 103 cases, or 94.1 per cent. of the former to 5.8 of the latter.

As to the question whether syphilis generally predisposes to epithelioma of the tongue it may be answered in the negative. Among von Winniwarter's 46 cases, 3 had been syphilised, and 4 had had specific sores without any constitutional troubles. Of our own 60 cases, 12 had clearly had the disease, 3 were doubtfully affected, and of 22 it is reported that there was plainly no evidence of its existence; in 24 there is no note on this point. In the 61 cases from the Middlesex Hospital, included in Mr. Morris's table, 13 are stated as having had syphilis, in 9 it is distinctly negatived, in 1 it is doubtful, and in 38 there is no note on the subject.

Instances, however, are met with occasionally where an ulcer caused by the breaking down of a gumma has gradually developed an unmistakable epitheliomatous character. This was well seen in at least one of our cases at University College Hospital, and the growth had to be removed. Here it is probable that the chronic syphilitic ulcer only acted as any other irritant upon a person predisposed to cancer in one way or another.

Physical characters.—The physical characters of epithelioma of the tongue now claim attention. The actual new growth itself, when fully developed, does not differ histologically in any important particular from squamous epithelial cancer of other parts, this being the form almost invariably met with here. We find lobulated prolongations of epithelial growths downwards into the deeper tissues and the same 'cell nests' as elsewhere. Nevertheless there are clinically, at least as far as my experience goes, four different initial forms of the affection which may revert sooner or later to the common type. These are: (1) the small, hard, sharply defined pimple or knot, a little raised perhaps, but smooth on the surface, first observed just beneath the coverings, but in the substance of an otherwise apparently healthy tongue, usually at one side or actually on its border; (2) the small abrasion or crack, more likely to be on the upper surface of the organ, starting without any previous induration, but very often from a blister; (3) the prominent or papillomatous form, looking benign at first, but developing into typical epithelioma later, seated as a rule on the dorsum of the tongue somewhat to one side and well back; then (4) a less frequent form, namely, a general rawness over a considerable area of the surface of the organ, with but slight induration at first, or, indeed, until the condition has lasted for a long time. This is a form which is often associated with leucoplakia. The two first of these varieties are the most rapid in their development into the deeper and more dangerous forms of the disease; the two latter are slower in their advance, and perhaps a little less liable to implicate the glands early. On this point our table speaks with tolerable clearness. Taking this implication of the neighbouring glands as a fair measure of the danger of any given growth, I find that out of 13 of our own table in which it is distinctly stated that the glands were not enlarged, 8 of the ulcers belonged to the large or medium sized superficial variety, while only 3 were of the large deep kind. And, on the other hand, out of 42 in which it is noted that the glands were implicated, only 11 were of the large shallow variety, while 26 were of the large deep kind, and 5 were small and deep, there being no glandular induration with the small shallow ulcers. The probability, then, of glandular infiltration appears to depend rather upon the depth of the morbid deposit than upon its superficial extent; in other words, we often see a large superficial ulcer with no glandular enlargement, while we meet with many small deep deposits with well-marked infiltration of the lymphatics. This also appears to have been von Winniwarter's experience generally, though he has not reduced it to figures, and Mr. Morris's tables afford grounds for similar conclusions, though here, too, a numerical estimate is difficult. In fact, we are always met with a great difficulty in supporting such conclusions by rigid statistical data, owing to the different methods of recording cases adopted by

various writers. But a careful study of large numbers of published cases, as well as actual examination of at least forty or fifty during life or after death, has satisfied me as to their general accuracy.

Familiarity, then, with these several initial forms of epithelioma in their earliest stage is of vital importance in view of speedy diagnosis and prognosis.

Seat of neoplasm.—The question as to what part of the tongue is most frequently the seat of cancer now suggests itself, and is of particular interest as furnishing some indirect evidence on the origin of the disease from local irritation. It is perhaps best answered by assimilating as far as possible the deductions on this point from carefully arranged tables, such as those furnished by von Winniwarter and Woelfler, and so securing as large a total of accurately recorded cases to judge from as possible. This is done in the following tables :—

	Von Winniwarter	Woelfler
Right upper surface	12	
Left upper surface	6	
Right border	5	15
Left border	9	9
Under surface	8	6
Tip of tongue	3	6
The dorsum	3	2
The frenum		6
The floor of mouth		4
	16	48

The mode of classification of the beginning of the cancer in the tongue adopted by Mr. Morris in his table being more in harmony with the classification I had already given in the text before I had the advantage of hearing his paper, I have thought it better to compare the figures from our own table with his material collected in a neighbouring hospital, than with those of the German authors above, which are arranged somewhat differently. I have, however, examined in addition into one small point, noticed specially in the German lists, as far as my own table goes—namely, the relative frequency of disease in the two sides of the tongue. Here, too, then, the right side is found to be more frequently affected than the left, but the difference is only slight, being as 21 to 18 out of 39 cases in which the point is noted. But other points of much more importance as regards the origin of the disease are given in the following table, and as the need of study of the disease as early and as closely as possible is urgent, I have given them rather in detail. The table is by no means perfect, but it indicates some matters well worthy of closer study. The earliest trace of the disease where a record has been kept has been noticed as follows :—

	Morris	Author
1. As a small fissure or crack	—	—
<i>a.</i> On the dorsum	4	—
<i>b.</i> „ tip	4	1
<i>c.</i> „ edge	20	3
2. As a pimple or small tubercle	—	3
<i>a.</i> On the edge	5	13
<i>b.</i> „ under surface	1	—
<i>c.</i> „ under surface and edge	1	1
3. As a nodule in the substance	5	5
4. As a blister	3	2
5. As an ulcer spreading from the floor of the mouth	3	2
6. As an ulcer spreading from the pillar of the fauces	1	—
7. As a general soreness or feeling of rawness, with fixation of the tongue	2	8
8. As an ulcer spreading quickly from wound or other cause	—	18
	49	56

The most remarkable fact deducible from these combined figures is the large proportion of cases in which the disease had its starting-point on one or other border of the tongue, equalling at least 41 in 105 cases. I may mention further that, although from the German collection and in our own the right side appears to have been more frequently attacked than the left, this is not the case in Mr. Morris's list, which I

have examined carefully with a view to this point. Here the disease started exactly the same number of times on the right as on the left, in 32 instances. In our own tables, it will be remembered, the two sides are thus represented—right 21, left 18.

Another point worth noticing is the large number of cases in which the disease commenced as a fissure or crack, or as a pimple or tubercle. And there is good reason to suppose that in many of those set down as first noticed in the form of an ulcer, the disease really started in one or other of these ways. This ought to teach us to regard all indolent fissures or pimples on the tongue (between the ages of 30 and 50 especially) with much suspicion, and to be ready to excise them freely on the first clear sign of their increase with induration. Many valuable lives would be saved if this were more attended to; it would matter very little if occasionally a small harmless pimple or fissure were excised, the operation required in such a case being very simple.

Again, the shallow, patchy, often multiple, slow-growing ulcers, which spring from one form of leucoplakia, are found in many cases in our table, and show very distinctive characters.

Finally, it may be mentioned that epithelioma, starting from an originally benign papilloma, is hardly represented in the above tables. And yet I have seen several apparently with this history. At the present moment I have one such under my care with now hopelessly advanced disease, both in the tongue and glands of the neck. This patient states clearly that seventeen years ago he distinctly had a growth, which, from his description, must have been a papilloma on his tongue. This was partially removed by a medical man, and grew again somewhat. Two months ago one of my colleagues removed a great part of his tongue for well-marked epithelioma which had started at the stump of the papilloma, but the man is now dying of recurrence.

Unfortunately, the ordinary practitioner often does not see these tongue cases in the early stage—indeed not, as a rule, until very considerable ulceration has taken place. And not until the terribly fatal error of delay in any case of the kind is more generally recognised will this cease to be so. Doubtless there is an improvement in this direction of late years, but still only too many patients present themselves to the operator in a state almost, if not quite, unfit from the extent of the disease, for any interference. Thus, in our own series of 60 cases, 22 were unoperated upon, of which nearly all are expressly stated to have been unfit for interference of any kind.

In the Middlesex Hospital list of 61 cases, too, there is even a larger proportion unoperated on—namely, 32 to 29 in which excision was practised. Now, if these 54 patients from the combined lists had been dealt with by excision and had survived immediate risks, there would have been an average gain of life to each of 6·1 months, as we shall see further on, making up a total of over 27 years of human existence saved, or over 50 years to every 100 patients, to say nothing of relief of suffering and possible immunity from recurrence.

It is speculation in this direction which has led some Continental surgeons to perform, as a matter of course very extensive operations on patients whose disease would in this country be held by most to be too far advanced to justify extirpation. Thus, in Professor Billroth's Klinik out of 94 cases only 7 were not operated on, the remainder in many cases undergoing the most severe operations. As might be expected, this has increased the mortality in that particular Klinik, but at the same time many lives have been prolonged and rendered tolerable which would otherwise have terminated miserably within a short period.

What all must hope for, then, is a more thorough acquaintance with the earliest manifestation of epithelioma in the tongue, and a fuller knowledge among the public of the gravity of the condition and of the fatality of the error of neglecting any suspicious appearance in the organ, even for a day.

Under whichever of the three forms mentioned above the disease makes its first appearance, it usually soon reverts to one tolerably characteristic type of ulcer. This is usually seated more on one side of the tongue than the other, and may spread over its border on to the floor of the mouth; it is irregular in outline, abrupt at the margin, which is much indurated and usually nodular, and a little raised and even

everted. The surface of this ulcer is usually very rugged, lumpy red granulations alternating with small whitish shreds of broken-down material. Sometimes the tongue is puckered around and bound down by firm material to the floor of the mouth. In advanced cases the whole of the tongue may be in great part destroyed, with more or less of the floor of the mouth, and even with part of the jaw. Again, the starting point of the growth may be the floor of the mouth or under surface of the tongue, the organ itself being only secondarily involved. Here the glands are almost certain to be early infiltrated. Finally, there are cases in which the initial lesion appears to remain stationary or even heal up, while a hard round knot of epithelioma forms in the substance of the tongue, where it may attain considerable size before actually breaking down upon the surface. If this mass develop at the side of the organ towards the floor of the mouth, the tongue may be more or less fixed and bound down.

The only condition with which this is likely to be confounded is that produced by the breaking down of gummatous or tubercular deposits. Gumma of the tongue, however, is usually seated more towards the body of the organ than in the border; it is generally present for a considerable time in the form of a smooth elastic lump, not affecting the superficial layers of the organ, and wanting the rugged hardness of the epitheliomatous nodule; it then softens, opens on the surface, and leaves a ragged cavity, at the bottom of which is a quantity of greyish slough. This cavity is not surrounded by induration of the tissues as in cancer, and its borders are not hard and everted. The glands along the margin of the jaw are not affected. Finally, a week or ten days' use of free doses of iodide of potassium will reduce it in size as a rule, while no effect will be produced on epithelioma.

The tubercular ulcer of the tongue is very rare as compared with the gummatous or cancerous. It is, as a rule, seated far back on the tongue, is often multiple, and is mostly, too, associated with similar ulcers on the palate or fauces. It is usually found as a sharp-cut cavity covered with a creamy white curdy deposit; it has a bright red margin but little indurated and not everted. Finally it is, as met with, mostly associated with other evidences of phthisis, and it will probably improve under the use of cod-liver oil and other tonics, with the application of Tr. Iodine to the ulcer.

All these forms of cancerous disease give rise to much suffering. They interfere with mastication, and, as a consequence, patients often prefer to confine themselves to soft foods or fluids for months, rather than suffer the torture of chewing and swallowing solid matters. Again, these ulcers give rise to much fetor and discharge, interfering greatly with the patient's comfort, and producing gastric and pulmonary disturbance in many cases. And not only do they complain of the discharge from the ulcer, but also in many cases of profuse salivation, necessitating constant spitting, which, as the secretions of the mouth are very foul, is most distressing. But, worse than all this, many unfortunate patients with lingual cancer suffer the most intolerable pain. This is not invariably the case where the disease is moderately advanced, some suffering but little then. But, when fully developed, few escape the greatest torture. This is usually felt, not only in the ulcer itself during eating, but constantly at other times in the ear, occiput, or radiating over the temporal region. When this pain is at its worst everything else is forgotten, and nothing but the administration of large doses of morphia, or division of the gustatory nerve (p. 618) or excision of the tongue, has any control over it.

OPERATIONS ON THE TONGUE.

We have now to consider what are the resources of surgery in dealing with these diseases described above. These naturally divide themselves into operations for the removal of portions of the organ, and palliative measures for rendering the patient's condition as little miserable as possible where, for any reason, the latter are not undertaken. All allusions here to the various ways of treating cancer of the tongue by caustics, &c., is purposely avoided. The practice cannot be too urgently deprecated. Only too often the surgeon has an opportunity of seeing the fatal mistakes which are still made in thus trifling with a most malignant disease by superficial applications of

this or that. And that moreover at a time when the patient could almost certainly be saved the risks of recurrence by timely excision.

The operations for the removal of portions of the tongue, which are of comparatively early origin, have become so numerous, and are so variously modified, that even a brief description of all of them would be impossible in a short essay like the present. I shall therefore do no more here than indicate the objects of the most important of the older procedures in a few lines devoted to each, arranged in a table, and shall then endeavour to give a short description of those methods of dealing with cancer of the tongue now most in use.

As to the propriety of operating at all for the removal of cancer of the tongue there can hardly be any doubt at the present day, although there is still a tendency in the minds of some surgeons to regard the operation with little favour. The question turns upon two points.

First, is it possible to rid a patient permanently of his disease who once has cancer of the tongue? This question is answered distinctly in the affirmative, as regards a certain proportion of cases, by statistics given later on (p. 605). But it may be answered with almost equal certainty from the natural history of epithelioma. Surely if there is one species of cancer more than another which remains for a time a purely local affection, it is this; and if there is a position in the body in which it can be isolated with ease, it ought to be the tongue. 'Why then,' it is urged, 'does recurrence take place in the vast majority of cases operated on?' as will be shown presently. The answer is that hitherto either the public has not been aware of the immense gravity of even the smallest trace of cancerous disease of the tongue, or the general diagnostic powers of our profession have not come up to the needs of the case in the early recognition of the disease, or the necessary knowledge that nothing but free and early removal of the part affected will secure a patient from recurrence is not as widely diffused as it ought to be; finally, there is a popular dread of removal of the tongue, based upon the belief that with the loss of part or the whole of the organ patients are bereft of the power of speech. That this is an unfounded fear has been already shown (p. 554). When this is better known generally, and also the fact that when epithelioma is taken early, removal of half the tongue will suffice to secure against its return, we may hope for less hesitation in seeking early relief.

But there is another aspect of the question hardly less important than that of the complete extirpation of the cancerous disease—namely, that even supposing in any given case we cannot hope to secure the patient from recurrence, the disease having been allowed to go too far, we may yet by free excision of the organ give very great relief for the rest of the sufferer's life, even if we should prolong it. It is now a well-known experience that when recurrence after such operations does take place, it is very rare for it to appear in any part of the stump of the tongue or mouth. The latter remain quite free from the disease to the end in a large majority of cases, while the glands of the neck or the internal organs become the seat of the finally fatal recurrence. Removal, then, of the tongue with the original disease frees the patient for the rest of his life from the unspeakable distress due to the presence in the mouth of a most painful and disgusting ulcer, and the dangers of hæmorrhage and septic infection always impending. This advantage of excision is felt so strongly by most surgeons who have had any large experience of cancer of the tongue that, even if the operation were never to give immunity from recurrence or even to prolong life, they would still advise its performance, knowing the comfort thus secured to the patient for the rest of his days.

All this, then, points in the same direction—namely, that the closest study of all morbid conditions of the tongue is called for, and especially those which appear to eventuate in epithelioma; and further, that all delay in dealing with the latter is fraught with danger, free removal being called for as early as may be, in order that all possibility of recurrence may be excluded, and that those very extensive excisions presently to be described, which are dangerous in many ways, may not be necessary.

Wide-reaching and elaborate operations are no doubt called for at present, and have done very good service hitherto, but the hope of the future lies quite as much

in improved and more generally diffused powers of diagnosis of commencing cancer of the tongue as in the further development of these.

What the difficulties and dangers of operations for the removal of the whole or part of the tongue are, whether for cancer or benign growths, cannot be better illustrated than by a table showing their history and development very briefly. It may be mentioned, however, that this table applies almost exclusively to measures undertaken for the extirpation of cancer of the organ, the latter requiring excision operations very rarely for other diseases. In compiling this I have availed myself largely of Just's¹ and Woelfler's² very valuable essays. Minor modifications of the chief methods are not noticed here; and yet the list is a long one, showing by the very number of the operations it contains that no one in particular has hitherto proved altogether satisfactory.

They may be divided into two groups—1. The earliest irregular procedures. 2. The definitely designed operations—as follows. —

EARLIEST IRREGULAR OPERATIONS.

1. Pimpernelle, died . . . 1658. Was probably the first to excise the tongue with success.
2. Marchetti . . . 1661. Extirpated a cancer of the tongue by actual cautery: probably the first recorded extirpation for this disease.
3. Valens Hoffmann . . . 1692. Removed a tongue affected with macroglossia.
4. Ruysch . . . } 1737. Excised with a knife and cauterised with a hot iron.
5. Memonista . . . }
6. Heister . . . 1742. Gave the first methodical description of operative treatment of cancer of the tongue.
7. Buxdorf . . . 1754. Excised a true cancer of the tongue with the knife.
8. Guthrie . . . 1756. Was probably the first English surgeon to excise a cancer of the tongue, using the knife followed by cauterisation of the cut surface.
9. Louis . . . 1759. Ligatured a 'fungus' of the organ, and later (1774) spoke at length and clearly in favour of total excision for cancer.

DEFINITELY DESIGNED OPERATIONS.

Ligature.

10. Inglis . . . 1803. Introduced ligature of the tongue from the mouth for cancer, the cords being drawn with needles through the tongue and round the tumour.
11. Major . . . 1827. Split the organ down centre to apply the ligature to the diseased half from the mouth.
12. Cloquet . . . 1827. Also split the organ, but introduced the ligature by a supra-hyoid incision, and strangled the diseased half.

Wedge-shaped Excision.

13. C. J. Langenbeck . . . 1819. Introduced wedge-shaped excision of diseased part of tongue, with careful suture of the resulting flaps.

Preliminary Ligature of the Lingual Artery.

14. Mirault . . . 1833. Introduced preliminary ligature of the lingual artery to give a clear bloodless field for extensive excisions. He was followed by Roux, and later by Roser.

Écrasement.

15. Chassaignac . . . 1854. Introduced the écraseur, employing Cloquet's supra-hyoid method, and defining it more exactly, i.e. using puncture in above spot instead of incision.
16. Middeldorp . . . 1854. Introduced the galvanic écraseur.
17. Nunneley . . . 1866. Introduced the supra-hyoid use of the écraseur into this country, adopting Chassaignac's modification.
18. Girouard . . . 1857. Employed circum-puncture with rods of caustic.

Division of the Cheeks.

19. Jaeger . . . 1831. Was the first to divide the cheek for free access to tongue.
20. Maisonneuve . . . 1858. Divided both cheeks from angle of mouth for the same purpose.
21. Collis . . . 1807. Re-introduced Jaeger's operation, using the écraseur.

¹ Schmidt's *Jahrb.*, 1830, p. 245.

² *Archiv f. klin. Chir.* v. Langenbeck, 1880, Bd. xxvi, p. 314.

Division of the Lower Jaw.

22. Roux, died . . . 1836. Was the first to divide the lower jaw and lip in mid-line, in order to gain free access to the floor of the mouth and tongue.
23. Sédillot . . . 1844. Improved this method by dividing the bone by a serrated cut.
24. Syme . . . 1857. Divided the jaw in mid-line, and excised with the knife.
25. Billroth . . . 1862. Divided the jaw and soft parts at the side in two places, and turned down the flap of skin and bone so formed, replacing and wiring the bone afterwards ('osteoplastic operation').
26. B. v. Langenbeck . 1875. Divided the jaw and soft parts opposite the first molar tooth on one side, in order to gain access to side of the mouth for removal of the tongue, glands, and part of the palatal arch and tonsil.

Infra-maxillary Operations.

27. Regnoli . . . 1838. Opened the floor of the mouth from below by an incision from middle of hyoid bone to chin, ending in another semilunar incision along the border of the jaw. The tongue, being drawn downwards and forwards through the opening thus formed, was excised.
28. Czerny . . . 1870. Modified this procedure considerably, forming lateral flaps.
29. Billroth . . . 1871 G. Modified it still further, extending both ends of the curved incision much further backwards, and omitting the incision in mid-line.
30. Kocher . . . 1880. Introduced a method of opening the mouth from behind and below the angle of the jaw to reach the base of the tongue, and remove it with all the lymphatic glands there situated.

From the above short review we see that the first aim of the earliest operators was the avoidance of hæmorrhage in dealing with the tongue; hæmorrhage which, from its position, would be both difficult to control and particularly dangerous on account of the proximity of the air-passages; hence the use of the actual cautery (2), the strangulating ligature (8, 9, 10, 11), the preliminary ligation of the lingual artery (14), the *écraseur* simple or galvanic (15, 16, 18).

When this danger had been more or less met, the more radical extirpation of the disease claimed attention, it having been found that recurrence beyond the root of the organ was frequent. Freer access to the deeper parts of the mouth was therefore sought either by splitting the cheek (19) or cheeks (20), or division of the jaw at one spot or other (21, 22, 23, 24, 25, 26), or by various sub-mental or sub-maxillary incisions.

Then when this requirement had been fulfilled and access to all parts of the root of the organ and mouth had been provided for, and the number of operations increased, the attention of surgeons became urgently drawn towards the necessity of guarding against the risk of septic infection which was found to be very frequent after these free operations. This was observed to take place either in the ordinary way from the wounded surfaces, or by the reception into the lungs of the products of putridity in the mouth during the separation of sloughs. To guard against these dangers, various modes of effectually draining and disinfecting the mouth were designed. And then access of pure air to the lungs was provided for by means of a preliminary tracheotomy opening, not to be closed until the wound was cleanly granulating, the mouth and nose being closed in the meantime. This prophylactic tracheotomy had already been introduced by Trendelenburg to obviate the risks of hæmorrhage into the larynx during the operation, but the idea of utilising the opening for breathing during this healing process, and thus increasing the facilities for antiseptic treatment of these cases, occurred apparently to the author and Professor Kocher of Bern simultaneously, and were put to a practical test by both at the same period according to the latter writer.¹

Finally the question of removing with the tongue all the lymphatic glands in and about the sub-lingual and sub-maxillary space, whether diseased or not, as a precaution against recurrence, has been raised lately, and an operation (30) designed to that end.

Of these various procedures it may be said generally that strangulation of the

¹ *Deutsch. Zeitschr. f. klin. Chir.* Bd. xiii. 1880, p. 147.

whole or part of the tongue by ligature is now abandoned almost entirely. The immunity from hæmorrhage which it gave was more than counterbalanced by the tediousness of the separation of the part, the distress to the patient meanwhile, and the great danger of sepsis during the sloughing process. The galvanic écraseur, too, although still used by some, is less and less employed in this country, and especially in London, by those who have much experience of operations on the tongue. It is found not to give immunity from hæmorrhage, to leave a more fetid sloughing surface than any other operation, and thus to increase the danger of sepsis, while it is troublesome and uncertain in use.

By far the largest number of extirpations of the tongue of any magnitude are now performed either with the knife, scissors, or simple écraseur, either chain (fig. 135), single wire, or twisted wire cord (fig. 136). And the results have improved, though probably not altogether owing to the less frequent use of the galvanic écraseur. At University College Hospital there would appear, however, to be some relation between the abandoning of this last instrument and the improvement. Thus from our tables I learn that of 16 cases operated on by the galvanic écraseur 8 died; while out of 17, where the wire écraseur was used, only 2 were lost.

Any of these instruments may be applied to the tongue in numerous ways. But to describe all those would lead us too far, and only the most usual methods will now be mentioned.

They divide themselves naturally into three groups: *firstly*, operations from the mouth, with or without division of the cheek or cheeks; *secondly*, through openings made by section of the lip and jaw; and, *thirdly*, through openings made by incisions beneath the jaw without division of the latter.

Fig. 135. - Chain Écraseur.

Fig. 136.—Écraseur for single wire or twisted wire cord

1. *Excisions from the mouth.*—For macroglossia, nævus, papillomata, or other benign growths, usually affecting the anterior part of the tongue, removal can usually be accomplished through the mouth. The part to be taken away can be included in a single loop of an écraseur and so divided very slowly; or, two chains or wires having been passed through the middle line from below upwards, the organ may be severed in two planes. Or, again, the knife or scissors may be employed either to sweep it off in one or more cuts, or, what is better, to remove it by two converging incisions (C. F. Laugenbeck *l.c.*) meeting in the middle line of the tongue, the resulting lateral flaps being brought together and stitched so as to form a pointed stump. In a case in which I assisted in removing a tongue recently by this method the resulting stump was most shapely, being well pointed and not too thick. This cut may be combined, in the case of very thick tongues, with two horizontal incisions, meeting in the same point (Boyer).

If the disease reach further back, the mucous membrane of the anterior attachments of the tongue, and the genio-hyoglossi muscles may be divided with a scissors at their insertion into the jaw (Paget); the organ thus freed may be drawn upwards and forwards out of the mouth to a considerable distance, and then dealt with, as just described, at a point much further back, the tongue being transfixed with a stout needle

FIG. 137.

a, Incision through cheek for removal of the tongue by Lauger's method;
b, Incision for removal at the base of the tongue by Kocher's method.

if necessary to keep the écraseur from slipping forwards. In this case, if only one half of the organ be but slightly diseased, it may in addition be split down its centre, and the side alone be taken away—an operation performed as early as 1827 by Major and Cloquet¹ using the ligature. This latter method of splitting the tongue into two halves has lately been revived and extensively practised by various surgeons.

Again a method of excision has lately been advocated by Mr. W. Whitehead of Manchester² which offers several advantages as far as it goes. It consists simply in excising the tongue from the mouth at its root with a curved scissors, snip by snip, commencing at the anterior attachments of the organ, while the latter is drawn forwards and upwards

out of the mouth, the insertion of the palatal folds being also snipped through in turn. The chief advantage of this method lies in the fact that there appears to be but little tendency to bleeding from the vessels thus cut slowly with the scissors. It frequently happens that no vessel requires to be tied from beginning to end of the operation. It has of course the disadvantage that it is not directed against the glands which are so frequently the seat of infiltration.

The scissors have also been in use in the same way for some years past elsewhere, and notably in Professor Billroth's Klinik, with very good results. But this operator generally takes the extra precaution of extirpating all the glands at the angle of the jaw by an incision at the side of the neck, sometimes also ligaturing the lingual artery besides.

¹ *Archiv. gén. de Médecine*, tome xiv. 1^{re} série, 1827.

² *Trans. Internat. Med. Cong.* 1881, vol. ii. p. 400.

But the belief that even this measure of cutting the anterior attachments of the tongue does not afford sufficient access to its deepest parts, has led many surgeons to enlarge the oral opening by incision of the cheek backwards from the angle of the lips. This was first done by Jaeger¹ in 1837 on one side, and later by Maisonneuve in 1858 on both. Jaeger's operation was revived a few years ago by Collis of Dublin² and is still employed by some, Professor Stokes of that city being a warm advocate of this method slightly modified.³ The incision in this case should be a curved one running from the last molar tooth downwards and forwards to terminate in the angle of the mouth (fig. 137 *a*). It no doubt gives very free access to the tongue, but it is fairly open to question whether, with disease so far advanced as to warrant such a severe measure, some of the operations mentioned below will not be preferable as giving more room on the floor of the mouth for wider excision of the part with the sub-maxillary and sub-lingual lymphatic glands then usually infiltrated. This has been felt by many surgeons, and they have resorted to other measures included in our second group.

2. *Excisions after section of the lip and jaw.*—Thus Roux in 1836 and Sédillot in 1844 divided the lower lip and *symphysis menti* in the middle line, and, separating the two halves of the jaw, removed the tongue freely (fig. 138 *b*). This operation was introduced into this country by Syme⁴ in 1857, and modified by him. In his first operation, beside section of the jaw, he divided the attachments of all the muscles running to the symphysis, whereby the larynx lost much of its support, and the patient became unable to keep it out of the way of the discharges trickling backwards from the floor of the mouth. In his second method the genio-hyo-glossi and hyoglossi alone were divided anteriorly, the genio-hyoidei remaining. He believed that in this way more power was left to the patient to raise his larynx and keep it out of the way of the putrid matters passing backwards which had been the cause of death, as he believed, of three

FIG. 138.

a, incision for removal of the tongue after section of the jaw in mid-line by Roux, Sédillot, or Syme's methods; *b*, incision for removal of tongue after section of jaw opposite the first molar tooth by von Langenbeck's method.

out of his four cases. The operation, though a comparatively easy one, is very severe, and can only be necessary where the floor of the mouth anteriorly (with or without the bone) is engaged in the disease. The soft parts are divided in the middle line from the border of the lower lip to the hyoid bone, and then the jaw, first drilled through from before backwards on either side of the symphysis, is sawn through vertically either in a straight or slightly serrated line (Sédillot), so that in the latter case they may interlock to a certain extent when brought together again. The insertions of the genio-glossi muscles being now divided with scissors, as well as the mucous membrane along the ramus of the jaw, the whole tongue is drawn well upwards and forwards and removed either by one sweep of a knife at its base or half at a time, which is better, giving but one

⁴ *Lancet*, 1857 and 1858.

lingual artery to deal with for the moment, or by the *écraseur* preceded or not by splitting the organ down its centre. The greatest immediate danger here is hæmorrhage with consequent suffocation. This, however, can be controlled with comparative ease in the wide gap provided by the division of the bone, and the vessel secured in the usual way with a ligature. If there be any difficulty in seizing it, the fingers should be passed down the pharynx by the side of the epiglottis, and the root of the tongue hooked by it well forwards and outwards against the angle of the jaw, when the vessel will be compressed until its orifice is seen and secured. This manœuvre, which I believe originated with my colleague Mr. Heath, is simple and effectual in such cases and gets over a great difficulty. In two cases in which I operated by Sédillot's or Syme's method myself, I found division of half the base of the tongue at a time remove all the difficulty of securing the lingual artery, which was found on the cut face of the half stump as easily as could be wished, the organ being held forward by the ~~cut~~ ^{cut} portion. When the latter was then divided, the finger in the pharynx, pulling the root forwards as above, brought the second vessel well within reach. The only real difficulty arises when both vessels are allowed to spout at the same time, each thus obscuring the other. After the tongue has been removed the two ends of the jaw are wired together by means of the holes previously drilled, and then the soft parts are brought together as for hare-lip, the lower angle alone being kept open by a drain tube.

Syme's operation being deemed defective in some particulars, especially in not giving a clear view of the deeper lateral parts of the root of the tongue, another mode of dividing the jaw was devised and practised by Billroth in 1867; but it offers few advantages which simpler operations do not possess, to counterbalance its severity. It consists in dividing the soft parts of the lip and face and the jaw at the side in two places by vertical incisions, and turning down the flap thus made, so as to gain access to the side of the mouth. The lingual artery glands and the tongue itself are thus easily reached; when these have been dealt with, the flap containing the side of the jaw is replaced and secured by wire sutures in the usual way. But the disadvantages of this very severe operation led Billroth to abandon it, and I do not think that it was practised to any extent by other surgeons. In 1875 von Langenbeck, on the other hand, divided the soft parts and jaw from opposite the first molar tooth downwards and forwards to the hyoid bone (fig. 138 *b*), and thus reached the most important aspect of the diseased region. On the removal of the latter, the bone was wired as in Syme's operation, and the soft parts united with sutures, provision being made for drainage. This procedure has not yet found much favour in this country, though I have heard of it being used lately. Nor does it appear to be employed extensively abroad. It would, however, be suitable in certain severe cases in which the disease lay far back and close to the floor of the mouth or jaw itself.

3. *Excisions through openings below the jaw.*—This leads us to the consideration of our third group of operations, including those by which the tongue and floor of the mouth are reached by incisions below the jaw. The first to plan an operation of this kind was Regnoli in 1838.¹ He commenced by making a curved incision under the border of the chin for about 3 inches, and another from the middle of this to the body of the hyoid bone (fig. 139). Through these the floor of the mouth was opened up and all the anterior attachments of the tongue were divided, the latter being then drawn well forwards and downwards through the wound, and removed with the knife. But it was found that Regnoli's method gave really but very limited access to the most important part of the mouth, in cases of cancer—namely, the base and lateral aspect of the tongue where the infiltration spreads. It was suitable, no doubt, for the removal of large non-malignant growths reaching far back, as in Regnoli's case, which was that of a girl of 15 years, whose tongue was the seat of what he described as a large 'tubercular' mass. Whatever this was, it most probably was not cancerous, in view of the age of the patient and the description of the tumour, and consequently the control of the base of the organ was of less importance, except as far as the vessels were concerned. This first sub-mental operation was then improved

¹ Schmidt's *Jahrbuch*, 1839, Bd. xxiv. No. 2.

upon by another, devised by Czerny with the aim of better reaching the side and root of the tongue. This consisted in opening the mouth from the side, a large triangular flap of the soft parts being formed with its base along the ramus of the jaw, and its apex at the hyoid bone. This flap was turned upwards on the cheek, and then, after preliminary ligature of the lingual artery, the tongue and all the glands in and about the digastric space were extirpated, after which the triangle of skin and soft parts replaced and sutured, due provision being made for drainage of the cavity of the mouth.

Billroth again modified Regnoli's operation by omitting the vertical cut, but prolonging the curved sub-mental incision much further backwards on both sides, so as to be able to ligature one or both lingual arteries before extirpating the tongue and its neighbouring lymphatic glands.

Finally, an infra-maxillary operation has lately been devised and practised by Kocher,¹ which appears to promise considerable advantages beyond the last two, and has hitherto given very good results. This consists in making an incision, commencing a little below the tip of the ear, down the anterior border of the sternomastoid muscle as low as the hyoid bone, then forwards to the body of the latter, and so upwards along the anterior belly of the digastric muscle (fig. 137 *b*, p. 600).

The resulting flap is turned up upon the cheek, and the lingual artery ligatured before it passes under the hyoglossus muscle. Then, commencing from behind, the glands and all the structures at the postero-inferior aspect of the tongue are removed, together with the latter, the opposite lingual artery, if necessary, being tied first from a separate incision. All this is performed under the antiseptic spray, and the large wound is filled either with Listerian gauze, or a sponge wrung out of carbolic acid solution, and left to granulate up without being stitched, the secretions, in the meantime, escaping into a loose external antiseptic dressing. This operation is only possible after a preliminary tracheotomy proposed by Trendelenburg several years ago for such cases, but first practised by von Langenbeck. This is the first step in the procedure,

after which the pharynx is carefully stuffed with a sponge wrung out of carbolic solution and held by a string. All fear of choking from blood being now over, the formation of the flap and excision are undertaken carefully and deliberately, chloroform being administered by the tracheal opening. Moreover, the patient is compelled to breathe solely by the latter, until the excision wound is healing well and cleanly. This last precaution was advocated and put in practice, as Kocher says, independently by him and the writer at the same time. And, from the experience I have had of it in several cases, I can speak very favourably of it, the patient breathing pure air all the time the wound is healing. But of the preliminary tracheotomy in any extensive operation on the tongue, I would venture to speak still more highly. Having been, I believe, the first to adopt the practice in this country, I have watched it with special interest, and am satisfied, after the experience of several cases in which I have adopted it, that the measure will take its place in surgery for certain cases. The comfort of operating when there is no risk of the patient being suffocated by his own blood, and when the state of the suspected tissues can be examined consequently without hurry, and any vessels easily controlled, can only be

FIG. 139.

Incision beneath the chin for removal of the tongue by Regnoli's method.

¹ *Deutsch. Zeitsch. f. Chir.* Bd. xiii., 1880, p. 147.

appreciated by those who have operated by both methods—*i.e.* with and without tracheotomy. The latter operation is comparatively easy when the patient is breathing quietly under chloroform, and does not itself, when thus done, materially add to the patient's danger. It will allow, too, of the wound being treated antiseptically from beginning to end, if we follow Kocher's method.

Choice of operations.—Among all the operations above enumerated the surgeon has a large choice for any particular case. And yet, as a rule, each appears to have a special liking for some one method as his routine practice. And here we find the greatest variety of likes and dislikes, one author advocating this measure and deprecating that as fervently and honestly as another will take the very opposite view. But, if we read the bulk of the most recent literature of the subject, we cannot help feeling that the origin of this diversity of choice lies probably in the different conceptions of the aims of the operation which exist in the minds of surgeons. Many appear to deal with epithelioma of the tongue as though to remove the purely local condition with immediate safety to the patient were their only object. Either this, or they are hopeless of doing more. Others, viewing the matter in the light of the experience that all ordinary operations upon the tongue alone for this disease are followed by almost inevitable recurrence in the neck (if the affection be anything more than just commencing), go a step further, and, while admitting that even to remove the local disease alone is most desirable, contend that, while there is any hope of freeing the patient from all danger of future recurrence, our operations should aim at this, even though they be much more extensive, and involve considerable immediate risk to life. Now, if the first object alone be had in view, many of the operations upon the tongue itself from the mouth will be quite adequate, the local cancerous disease will be removed with but little risk on the whole, and will not recur, *in the mouth at all events*, except in rare instances. But it will recur in the lymphatic glands in an enormous proportion of cases. This last is no loose statement, but appears from an examination of a very large mass of recorded facts as well as from the observation of a considerable number of cases operated on by my colleagues and myself at University College Hospital. This being so (as we shall see presently from an examination of the statistics of the operation), surely we are justified in undertaking very extensive operations on the tongue and its surroundings, and in running considerable risk in the hope not only of removing what is palpably diseased, but also those tissues around, of which we know that in ninety-nine cases out of a hundred, if they are left, they will develop the disease later on. That the whole tongue should be removed except in cases where there is but a small nodule clearly localised in one border of the organ, is quite decided. The risk of leaving a little disease behind in the remaining half is too great to justify such conservatism. And the results to the patient as regards eating and speaking are as good, if not better, after total extirpation, as after removal of one half. It has been noticed that the scar down the centre of the mouth, where half is left behind, often interferes materially with the movements of the latter. Still with disease of small extent, limited to the border of the organ as far as the fear of recurrence is concerned, we need not go far beyond the middle line; for the track of the lymphatics is for the most part away from the latter towards the root.

Frequency of recurrence.—That recurrence *has hitherto been the rule*, after the ordinary operations for cancer of the tongue, I venture to think I am justified in stating from the following considerations:—I have before me five series of cases, in which full particulars of the operations and their results are given as accurately as could be. These make up an aggregate of 170 individuals upon whom extirpation of the whole or part of the tongue for cancer was performed. To these I might add a very large number of cases collected from journals, &c.; but for the object in view we shall approach nearer to accuracy by taking only completed series where aggregates of individual operators or institutions are given without omissions. The above total of 170 includes 87 patients under Billroth during 1867–1880 inclusive; 38 at University College Hospital during 11 years (1871–1881 inclusive); 14 by Prof. Kocher; 9 by Prof. Rose of Zürich (1861–1875); and 22 at Middlesex Hospital. In this large number I only find 17 cases of non-recurrence after an interval of a year

as follows: 9 from Billroth's Klinik after $1\frac{1}{2}$, $5\frac{1}{2}$, $1\frac{1}{2}$, 3, 3, $3\frac{1}{2}$, $2\frac{1}{2}$, $2\frac{1}{2}$, 1 years respectively; 2 from the Middlesex Hospital table after $2\frac{1}{2}$ and $1\frac{1}{2}$ years each; 1 by Heath after 10 years; 4 by Kocher after 14 months, 5 years, 5 years, and $6\frac{1}{2}$ years respectively; and 1 by Prof. Rose after 2 years. Others, of course, may have recovered and been lost sight of, but it is always usual for the successful cases to come to the surface. Be this as it may, the above figures are significant.

But, even if we search the whole literature of the subject, and accept allusions to cases not fully recorded, but stated on good authority to be cured, we find but very few cases of immunity for any number of years from recurrence after this operation. In addition to the above, I have only been able to collect 25 out of some hundreds of operations. Thus Weber¹ quotes a case by Travers with no recurrence after a year; 1 Chelius, in which the patient lived 12 years; and 2 by himself, well at $1\frac{1}{2}$ and 2 years respectively. Again Kocher² quotes, besides his own four cases, 1 by Simon, free after 12 years; 2 by Lücke, after a year; 1 by Baum, 'out of all his operations; 1 by Esmarch, after four years; Winniwarter another, operated on by Schuh, after 13 years; then Schlaffer³ mentions a case operated on by Rust, in which there was stated to be no recurrence. Further, Professor Verneuil⁴ states that, out of about 200 excisions he had done, he could only regard 4 as cured. Then Whitehead⁵ alludes to 1 case of his own, where there was no recurrence after 9 years; 1 by Buchanan, after 15 years; 1 by Nunneley, after 1 years; 4 by Hutchinson, after from 3 to 4 years; and 1 by Lund, after over 2 years. Finally, Stokes mentions two cases, operated on by himself, where no recurrence had taken place after 22 and 18 months respectively.⁶

And even though we should accept as beyond every doubt that these were all cases of true epithelioma, we have in this aggregate of 12 a very small percentage of permanent recoveries on the total of operations (which amount to several hundreds) performed by the whole group of surgeons whose names have just been given. Nevertheless some of these, about which there could be no question, must encourage us, showing, as they do, that cancer of the tongue can be completely extirpated beyond all danger of recurrence. What the exact proportion of permanent recoveries to the operations undertaken really is, it is impossible to say; the above figures are only given as suggestive as far as they go. When more accurate records are kept at our larger hospitals generally, we may hope for much light upon this subject.

As to which of the various methods of operation can claim the largest number of the above 12 cases of non-recurrence, I find it difficult to speak positively for want of accurate details. But this much is significant, that the surgeon (Kocher) who can show the largest percentage of permanent recoveries on the total of his operations (1 out of 14) is one who is not content with removing the diseased tongue alone, but also takes away all the tissues lying between it and the submaxillary lymphatic glands, as well as the latter themselves as far even as close to the carotid artery. Moreover operating by this, his own method (see p. 603), he has only lost one patient, and this apparently by an accident. Again, in Heath's case the operation was an extensive one, with removal of part of the *symphysis menti*. But, although it is not safe at present to institute a comparison based upon scanty statistics as to the relative immunity from recurrence to be expected from the different methods of operation, I incline to the belief, from study of recorded cases, that in the future we shall have vastly better results in this respect from those in which the lymphatic glands belonging to the tongue are systematically and regularly removed with the latter, whether they be palpably diseased or not, than from any others.

Of course this whole question turns upon our estimate as to when a patient can be considered as really beyond the danger of recurrence. This is a difficult point to determine positively; but, so far as our general knowledge goes, it seems tolerably safe to infer that, if there be no trace of the disease a year after operation, the patient may be pronounced free of the disease. Cases, however, are on record where, after as many as

two and a half or even thirteen years after removal of the tongue, disease has started again in one or other part of the mouth. (Schuh's case mentioned by von Winniwarter.) Whether this last and other similar cases are to be regarded as recurrences or not, the future must decide. It appears probable that they are rather a fresh and independent development of the disease in a patient with a strong predisposition to cancer.

Does operation prolong life where recurrence takes place?—Another point now claims our attention before going further: namely, whether, in cases where permanent cure does *not* result, the operation of extirpation of the tongue can be regarded as prolonging life. To estimate this, we must first know what is the average life of a patient affected with cancer of the tongue not operated on, from the first appearance of the disease until it destroys him. Observations in this direction, conducted by independent observers, have hitherto led to tolerably uniform results. Of the 22 cases from my own list not operated on, only 3 died in hospital, and the duration of life had not been traced in the rest. In those three, however, death occurred on an average of 13.0 months after the appearance of the disease, and are tabulated below as far as they go.

	NOT OPERATED ON		OPERATED ON	
	Number of cases traced	Average on these in months	Number of cases traced	Average on these in months
Paget	--	22.7		35.0
Anger		11.0		21.0
Clarke	25	10.5	11	21.5
V. Winniwarter	4	13.0	11	19.5
Author	3	13.0	4	18.5
Morris	17	10.5	15	16.5
Woelfler			10	19.2
	49	11.7	51	19.0

In the above list we find 49 cases from which to judge of the length of life without operation, reckoning from the first appearance of disease until death; and on these the average is found to be 11.7 months. On the other hand, the average duration of life in 51 cases operated on, stands at 19 months, showing a clear gain from operation of 7.3 months. If to these figures we add the computations of Paget and Anger, as above, where the number of cases is not given, we find the averages altered to 13.9 and 22.0 months respectively, or a gain of 8 months. The first sets of figures, however, from all I can learn, are probably much nearer the truth than the latter, which appear to place the duration of life too high in both instances. I have thought it well to give them, nevertheless.

From these figures, which represent the deductions of several independent observers, it would appear that life is prolonged by about seven to eight months by operation for cancer of the tongue. This would, in the minds of many, justify very severe operations, even supposing there were not the possibility of the disease being completely eradicated thereby, as we have seen it has been in certain cases.

Now, as a set-off to these advantages of extirpation of the tongue, there are the grave dangers attending the operation to which we must not shut our eyes.

Mortality after excision of the tongue. In order to gain a general idea of these, we may in the first place glance at some of the larger recorded series of cases where the whole results of an operator, an institution, or a particular operation are given without selection of cases. In examining the gross mortality in these, we shall be able to form a fair estimate of the general dangers of removal of the whole or part of the tongue for cancer. And here it may be remarked that it is almost impossible to classify operations on the tongue, according to the amount excised, with sufficient exactness to justify a strict statistical comparison of the dangers incidental to the removal of one quantity or another. I shall therefore include in the groups of cases to be examined all operations undertaken for the removal of cancer of the tongue, which have been anything more

than the snipping of a fragment of the organ from the mouth. Afterwards an endeavour will be made to point out some of the relative dangers of the various procedures.

Taking the operations of Billroth's Klinik for cancer of the tongue first, we find a gross mortality on 100 individuals of 26 per cent., or on 119 operations upon these, 22·6 per cent. This list embraces all his operations during the years 1860-1880 inclusive. In these numbers those operations performed before October 1867 are also taken into account by Woelfler, from whom I quote these particular figures. I have not mentioned these before in other computations, not having the details before 1867 at hand. From our own table, including all extirpations performed at University College Hospital, and amounting to 38 during the eleven years 1871-1881, I find that 10 died, or 26·3 per cent.; but of the last 18 cases operated on since January 1877, only 2 have been fatal, or 11·1 per cent. Kocher and Rose's series combined, amounting to 23 cases, show only 2 deaths, or 8·6 per cent.; and the Middlesex Hospital list on 29 cases, only 3 per cent. In Whitehead's series of 28 cases of his own operation in the hands of different surgeons, he states the mortality at 21 per cent. at the highest computation. Here, then, we have a total of 218 individuals who underwent extirpation of the tongue for cancer, representing the work of several German and several English surgeons for some twenty years; and of these the average mortality was 16·9 per cent. The differences in mortality between these several lists may be explained in great part by the differing gravity of the operations included in each. It would be possible to collect a much larger number of cases from journals, &c.; but such a collection would not form a trustworthy basis for estimating the danger of removal of the tongue, and I have preferred to take some of the most carefully recorded series I know of, all operated on within the last twenty years. Now, a loss of 16·9 per cent. of patients after any operation must always be considered a very grave mortality, and every effort must be made to reduce it. And it is reassuring to learn from an examination of the tables, including the results of a series of years, that those operations which fall within the last five do show a much lower proportion of deaths than those of the preceding fifteen. Those anterior to the beginning of our last decennium were still more fatal. Thus, Syme lost 3 out of his 4 cases.¹ Again, during the first six years of our own table, the mortality was as much as 40·4 per cent. on 20 cases, while in the last five it has fallen to 11·1 per cent. on 18 individuals. A similar improvement is apparent if we examine Billroth's series. Here we find 56 patients operated on between 1860-1876 inclusive; of these 17 died as a consequence, equalling 30·3 per cent., or 25 per cent. on the number of operations performed. Or, again, in the same practice from 1871 to 1876 inclusive, 42 individuals were operated on, of which 17 died as the result, amounting to a mortality of 40·4, or 36·1 on the operations performed on these 42 patients. Now, in contrast with these figures, we have the statistics of the same Klinik for the years 1877-1880 inclusive, and these show a very material improvement. There were, namely, 44 patients operated on in the corrected table. Of these, 9 died as a consequence, equalling only 20·4 per cent., or 17·6 per cent. if we reckon the number of operations performed on them. Moreover, since then the results in Billroth's Klinik have still further improved, so far as the number of cases go, as we learn from a recent article on the subject, for which we are again indebted to Woelfler.² In the series of cases here recorded, amounting to 17, there has not been one death: a result attributable manifestly, as will appear from a perusal of the clinical notes, to the greater success in the after treatment of the operation wounds. In this direction a most important advance has already been made in the Vienna Klinik; and this, owing to a careful study and appreciation of the dangers of this particular class of operations. In this country, too, a very great improvement here has also taken place. At University College Hospital, for instance, there have been lately far less of those after complications, which used to be so dreaded, than formerly.

Now, if it be asked to what is this decrease of mortality of late years due, it may be replied generally that it is rather to a better understanding of what the dangers

¹ *Lancet*, 1857, 1858, 1865, 1866; and *Med. Times and Gaz.*, 1865.

² *Archiv f. klin. Chir.*, Bd. xxvii. 1882, p. 410.

incidental to tongue extirpation really are, and the way to avoid them, than to any decrease of severity in the operations performed; for, if anything, the latter have on the whole become more extensive. These risks have already been alluded to generally (p. 598), and must now be regarded a little more closely.

Special dangers of excision—It was stated above (p. 598) that the greatest dangers in operations on the tongue were: *first*, bleeding; *secondly*, sepsis of the ordinary pyæmic form; *thirdly*, lung affections produced by the mechanical entrance of foul matters into the air-passages from the unclean wounds in the mouth. The first of these has always been recognised; the last two have gradually become better known, and whether confounded clinically one with the other, as is often the case, or regarded as distinct affections, have at last come to be considered as the most important of all.

Bleeding.—Now, when bleeding is spoken of here as a danger, it is not in the usual sense; i.e. that the actual loss of blood, primary or secondary, is to be feared: it has rarely or ever proved fatal in this way. It is rather that the blood poured out into the cavity of the mouth finds its way very easily into the air-passages during inspiration, and leads to suffocation or (contaminated with the septic discharges from the mouth) to putrid inflammation in the lungs. Before the use of chloroform this was not so much to be feared. The patient, as in Syme's first operations, was placed in a sitting posture by which most of the blood flowed forwards, while any that flowed backwards was coughed up. But now, with the patient on his back, a very little fluid in the mouth is quite sufficient to cause danger from trickling into the larynx, from which it is not expelled owing to the feeble expiratory efforts resulting from the narcotic. It is rather sucked further and further into the smaller bronchi. But it may also be suddenly poured out from a cut lingual artery in such amount as to threaten immediate suffocation and require laryngotomy on the moment, as occurred in four cases at University College Hospital, one of them under my own care. The difficulty of at once catching the vessel lies here in the fact that either the latter is quite obscured by the collection of blood which it suddenly pours over itself, or, the two arteries being cut together, one rapidly covers the other with its blood.

This danger has been variously met from time to time: at first by the use of the strangulating ligature or actual cautery for the removal of the tongue; then, later, by the use of the *écraseur*, either galvanic or simple; then by trusting to ligature on the face of the wound after removal by the knife where a preliminary tracheotomy had removed the risk of suffocation; and, finally, by the revival of an older operation—namely, preliminary ligature of one or both lingual arteries.

Of the different merits of these various procedures it would be impossible to speak at length in an essay such as the present. It need only be said that the galvanic *écraseur* does not give immunity from hæmorrhage, either primary or secondary. In two of the cases referred to above, where laryngotomy had to be performed on the table for bleeding, this *écraseur* was being used by most experienced surgeons. And in other recorded cases we find the same trouble arising.

Nor does it secure against secondary hæmorrhage, as is seen by a perusal of recorded cases. And yet this instrument is spoken of very favourably by other surgeons. But it has disadvantages, apart from the question of bleeding, which condemn it in the minds of the majority, especially the extent and great factor of the resulting slough, so that of late years it has come to be very little used.

The ordinary *écraseurs*, however, are still much used, especially in this country. Various forms are employed—namely, the chain (fig. 135), the single wire, or the wire cord (fig. 136). Of these the last is best, especially if that fine twisted cord be used, introduced to the notice of the profession by Mr. Barwell. The chain is, on the whole, clumsy and apt to 'kink,' even though it be flexible in a double sense, as in the most recently improved French instruments, where the articulations are doubly jointed. The single wire, on the other hand, tends to cut too rapidly through the soft tissues, while it may not divide or crush the vessels at all in the last loop it forms as it passes through the eye of the stem. Thus the lingual vessels and nerves are often drawn out uncut in a long wisp when the wire was quite 'home' within the stem of the instrument; and this where there was no undue hurry. The wire cord,

on the other hand, cuts less evenly and rapidly, and can be made to form a smaller loop as it passes through the eye of the stem, so that its effect on the vessels is more thorough.

Ligature of the lingual artery on the face of the tongue stump is perhaps not so difficult if but one half of the organ be divided at a time, the whole being drawn well forward by a finger hooked round its base in the pharynx, as recommended by Mr. Heath. Of the value of this last measure I have convinced myself practically in more than one operation. Cutting one half at a time with a scissors, snip by snip, appears to give time for the arrest of bleeding very effectually, as we learn from Whitehead's series of cases operated on in this way. Latterly, preliminary ligature of the lingual artery has been very freely practised abroad and with the best results by (Woelfler¹ Kocher²); and in a case in which the writer has recently adopted the practice, he has found it most satisfactory. It has the advantage of making sure of the lingual vessels; and, as it can be combined with extirpation of the lymphatic glands at the root of the tongue, it will probably come more into favour still, especially as advances in anti-septic surgery in this region have removed to a great measure the dread of extensive burrowing of matter in this part of the neck. Finally, one of the aims of preliminary tracheotomy, introduced by Trendelenburg, has been to reduce the danger of inspiration of blood into the lungs during operation, and so remove the source of anxiety to the surgeon while performing an operation which calls for deliberate work in all cases, and especially if we are aiming at the removal of lymphatic glands at the root of the tongue. And I venture to think that any surgeons who have adopted this line of practice for serious cases, will agree that the comfort of dealing with the diseased region without any risk to the patient from sudden suffocation with his own blood, makes up for any slight addition to the whole operation. I have only employed this measure four times among my own cases, but, as far as this experience goes, it leads me to think very highly of it. In my last two cases I regretted not having done a preliminary tracheotomy; for in the first of these I was obliged, just as the wire cord *écraseur* began to cut, to perform laryngotomy in a hurry on account of asphyxia from bleeding, and, although the patient recovered well, I regretted that I had not begun by opening the windpipe. When the latter is open, and a carbolic sponge is firmly jammed in the pharynx (which is to be preferred to the india-rubber bag tampon of Trendelenburg), the patient breathes easily through the cannula, and neither blood nor mucus can enter the larynx. It is in such a case immaterial what instrument is used to remove the diseased structures as far as any bleeding is concerned, and the surgeon can examine the suspected area at his leisure as he proceeds with his extirpation. When the knife is used for the latter, it has the advantage that the tissues around are not bruised or otherwise altered, as with either of the *écraseurs*, and thus the search for any secondary deposits can be conducted with more certainty.

It is objected to this procedure that the risks of tracheotomy, immediate and remote, are added to those of excision of the tongue. But the immediate dangers of opening the windpipe, when a patient is breathing quietly under chloroform, are not to be compared to those incidental to the operation when there is struggling and gasping for breath, as in the condition for which we are most commonly called upon to interpose in this way, and it is a mistake to compare the two operations. And if I may venture to cite the experience of four cases of preliminary tracheotomy, I may say that they were as easy operations as one could wish, and a great contrast to others I have done in a hurry for imminent asphyxia. As to the remote dangers of tracheotomy, they may be regarded as of less moment in the adult with strict cleanliness and otherwise careful nursing, and they are more than counterbalanced by the advantages to the surgeon in dealing with the tongue and the elimination of other immediate and remote risks to the patient, especially by freer and more deliberate removal of the infiltrated parts.

Septic lung affections.—We come now to the consideration of the other two

¹ *Archiv f. klin. Chir.* Bd. xxvii. 1882, p. 419.

² *Deutsche Zeitsch. f. Chir.* Bd. xiii. 1880, p. 146.

dangers connected with extirpation of the tongue—namely, pyæmic lung affections and those produced by direct infection of the lung tissue through the air passages. These have often been spoken of together; and, before showing that they are clinically distinct conditions, as I think will appear, it may be well to examine what proportion of patients fall victims to them (taken together) in a total of fatal cases. In order to estimate this approximately, I have for a long time past been collecting all the deaths from primary extirpation of the tongue which I could find accurately recorded. The list of those before me now includes 52 fatal cases taken without choice from the experience of a large number of operators, home and foreign, operating by the most various methods. A few others I have come upon might be added to these; but, as they are only mentioned without any accurate data being given further than that they died of 'pneumonia,' I have thought it unnecessary to include them, and have preferred rather to deal with a round number of 52 more accurately recorded. Of some of these it will be seen that points are lacking which it would be interesting to know, but without these the table is sufficiently instructive and very suggestive.

The first thing to be noticed in the following table is the very large number of deaths after excision of the tongue attributed to pulmonary affections. Of those who died, the lungs were deeply involved in 30. Now, of these the fatal affection is described as 'pneumonia,' 'bronchitis,' or 'broncho-pneumonia,' or 'gangrene of the lung' in 21, the rest being set down as 'pyæmia with abscess in the lung.' Then there are 4 deaths referred to 'pyæmia'; 2 of these (10 and 37) are without note as to the state of the lungs on the day after operation on which the patient died; another (36) shows the lungs to be healthy (a case of my own); in the fourth (48) they were plainly only secondarily involved. Next we have 6 put down to 'septicæmia,' 'septo-pyæmia,' or 'sepsis,' without lung affections being mentioned. The remaining 10 deaths arrange themselves as follows: collapse 3, exhaustion 2, shock 1, asphyxia from falling back of root of tongue 1, fatty heart (probably shock) 1, wound diphtheria, &c. (? septicæmia) 1, ordema glottidis 1, erysipelas 1.

The next point that strikes us is the very early appearance of those symptoms which preceded the fatal result in those 21 out of the 30 in which disease of the lungs is described as the chief factor. On an average of 13 cases where this point is mentioned these symptoms set in on 1·7 day. Also the shortness of life when these had once appeared is remarkable, only equalling 7·7 days calculated from the same 13 cases, or 7·6 if 20 in which this point is noted be used.

Again, it is worthy of note that those cases set down as dying of 'pyæmia,' with or without abscess of the lung, developed bad symptoms at a much later date, and lived far longer than the last group. Thus the dangerous symptoms set in 11·3 days after operation on an average of 6 cases where notes on this point are given, and the patients lived (in 7 cases) on an average 25·4 days. And if we take one of the cases where the lungs were found healthy, while there were distinct pyæmic abscesses elsewhere, we find that the bad symptoms set in on the 14th, and the man lived until the 55th day. Again in another of these 7 cases, where the lungs were manifestly only secondarily involved, the symptoms set on the 18th, the patient lived until the 24th day.

Now, although I should be sorry to base an argument positively on the above figures alone, extracted from a table compiled from such various sources, and probably differing considerably as to nomenclature, still they suggest conclusions similar to those which may be drawn from clinical observation. In a considerable number of cases terminating fatally not only after operations on the tongue alone, but those directed against other parts connected with the air passages (mouth, jaw, larynx), which I have had an opportunity of studying during life and in the post-mortem room, I believe I have observed two distinct kinds of fatal disease, which would correspond to the groups suggested above. One, a rapidly fatal form of lung inflammation peculiar to operations on any of the air passages, and due to the direct irritation of the pulmonary tract by septic products; the other, a less rapid but equally fatal form of disease possessing the characters of ordinary surgical pyæmia or septicæmia, and with or without any damage to the lung. If the latter exist here, it is only a late

complication, and quite secondary to the general condition, and not the immediate cause of death usually; whereas in the first group the affection of the lung is the primary disease and the immediate cause of the fatal issue.

Again, it has always appeared to me, judging from the cases I have seen—and I think I am borne out by the published notes of others—that within the first group there are clinically two varieties, both produced by direct inoculation, but differing somewhat as to the mode of production, as well as in the condition found in the lung. One appears to arise from the direct infiltration of portions of the lung, with foul matters in a fluid form making their way down one or other bronchus—'Verschluck-pneumonie' of the Germans. The other seems to be due to the constant inhalation of the intensely fetid and irritating gases produced by putrefaction where there is death of tissue in the mouth after operation; but where we have no evidence of the fluid products of the latter having found their way into the bronchi. In the first variety we usually find *post mortem* a number of small, foul, fairly limited abscesses; in the second, a widespread diffused inflammation running into absolute gangrene over large areas.

Now if this be a correct view to take of the nature of what may, perhaps, for the present be called 'surgical pneumonia,' as distinct from secondary (probably embolic) abscesses in the lungs as the result of ordinary pyæmia, we must have three great aims in view in the after treatment of our excisions of the tongue, if we wish to eliminate the greatest dangers of this operation. In the first place we must operate with the strictest antiseptic precautions possible, so as to avoid the risks of ordinary pyæmia; then we must do so in such a way that the fluids produced in the wound of the tongue and mouth shall either be kept from decomposition or drained away from that cavity, so as not in any way to reach the air passage; thirdly, we must go beyond this, and either render the air inspired through the mouth pure, or provide an entrance to the bronchi which shall eliminate the necessity of breathing by the mouth at all.

And I think that this view will be found to be correct by those who follow a number of these cases clinically, and afterwards examine the lungs.

Cases belonging to the *first variety* will generally exhibit the following features. A patient whose tongue has been excised progresses very favourably for the first day or two, his temperature, pulse, and respirations being little if at all above normal. He then becomes troubled with the accumulation of frothy mucus and saliva from the mouth, nose, and pharynx, which he finds a difficulty in swallowing and a far greater difficulty in spitting out. What comes from the mouth is very abundant, and is mixed with the secretions from the wound. The tendency to decomposition in this is very great in all but the smallest operations (where it can be constantly spat out or swallowed with ease), and, as a rule, unless strong antiseptics be used with the greatest perseverance, it becomes abominably fetid, especially about the end of the third day or so, when separation of sloughs begins. The patient now finds great trouble in clearing his mouth and pharynx of the viscid secretions accumulating, and generally complains of their tending to suffocate him. Do what he will, he cannot clear his throat and larynx of what lies around. On about the 4th or 5th day, then, he complains of troublesome cough, and temperature and pulse run up with the respirations. These symptoms become rapidly worse, the signs of pneumonia appear as in an ordinary case; then the patient suffers the most acute dyspnoea, becomes cyanosed, and usually dies about the 8th or 9th day.

When the lungs are examined in such a case the first point noticed is the horrible fætor which they exhale. We find the trachea and bronchi, as a rule, deeply congested, and in the parenchyma of the organ numerous small abscesses, distinct from one another with ragged gangrenous walls, and an area of discoloured oedematous pulmonary tissue around. In addition to this there may be patches of pleuritis over the damaged areas.

As an instance of the *second variety*, let us take a case of this kind which may be considered as typical. It is that of a man, aged 58, strong and healthy, operated on in 1876 for epithelioma of the tongue by Syme's method. For the first few days he felt so very well that he asked leave to get up and remain by the fire. His

mouth, however, became intensely fetid, in spite of all the means I could then contrive to prevent it. He was not particularly troubled with saliva and mucus, as there was a drain-tube in the floor of the mouth, but the fœtor was horrible. On the 7th day he complained of cough, which rapidly became troublesome; soon after his breathing became very short; he then became cyanosed, and died on the 9th day. I was away when the body was examined, but the cause of death is described by Mr. Gould, who made the necropsy, as 'broncho-pneumonia.' But from several other cases (under different operators), similar clinically, in which I have examined the lungs after death, I have found intense congestion of the bronchi, and then extensive gangrene of the lung over large areas, without any actual abscess perhaps. The pulmonary tissue has presented the appearance rather of having been killed *en masse* over large areas, and without a great amount of previous consolidation, or present softening and breaking down. These appearances are the same as those observed by others in similar cases. The part affected is of a greenish-brown colour, and looks more flabby and oedematous than solid. Here there will probably be less lymph exuded on the surface of the organ, but there may be a considerable amount of serosity in the pleura. The fœtor of this, as well as that of the lung itself, is something beyond description.

These two varieties of disease then differ from that form of lung affection produced in the course of ordinary pyæmia, where abscesses form in the lung substance, in being apparently the result of direct irritation of the respiratory tract from without, and not the sequence of any general blood condition as in the latter disease. They differ also clinically in coming on much earlier, in not being usually accompanied by rigors (only noted in one of the cases at our hospital), and in having a steady high temperature. They are equally fatal, death occurring at even an earlier date in surgical pneumonia than where pyæmic abscess of the lungs kills, even if the latter should be the immediate cause of death, which is not necessarily the case.

Treatment after excision.—It is unnecessary, perhaps, to follow these affections further in an essay such as the present. Enough has been said to show the greatest risks from extirpation, and to form a basis for conclusions as to subsequent treatment after this operation. Here, if anywhere, we must be antiseptic surgeons, carrying the principles as far as we can, even to the protection of the air inhaled from contamination and the cleansing of the mouth from particles of food which might remain about the wounded part. Again, we must secure as far as possible against the entrance of blood into the air-passages during operation, remembering that in most cases of cancer of the tongue there has been a foul ulcer in the mouth for weeks or months, and that blood passing from the mouth into the bronchi will bear mixed with it some of the discharge of the latter squeezed out during the operation; also, that blood so inhaled, though possibly pure at first, may become later on a nidus for putrid fermentation by the inhalation of impurities. That such contaminated blood is capable of exciting the most fatal lung inflammation is beyond all doubt, both from clinical observation and experiment. I have seen it produce gangrenous abscesses of the lungs and death in two days in a case operated on by one of my colleagues. In this case the discharge from the fresh wound would hardly have become abundant in so short a time, and as the blood was known to have entered the bronchi freely during operation, so that the patient was only barely saved by laryngotomy and sucking out blood from the trachea, it is fair to suppose that the scattered gangrenous abscesses were caused by the contaminated blood acting directly upon the lung tissue.

Since writing the above, some recently published experiments by Woelfler¹ have come under my notice, which confirm what has just been stated in almost every particular. These experiments (which should be studied by every operator on the mouth or any of the air-passages) were undertaken with the object of determining:—1. Whether the lungs were readily inflamed by the injection into the trachea of aseptic fluids, such as milk, wine, solutions of perchloride of iron, or carbolic acid or fresh saliva; 2. Whether the same injection with putrid fluids, such as maceration

¹ *Archiv f. Klin. Chir.* Bd. xxvii. p. 438.

filth, and rotting ox-blood, mixed with equal parts of water, was hurtful, and, if so, how; 3. Whether the admixture of iodoform with these putrid fluids modified their effects on the lungs. The first point was decided in the negative; the aseptic fluids produced no ill effects on the lungs. The second question was answered in the affirmative; the very same lung affections were produced as those mentioned above, and ran the same course. The result of the third line of investigation was perhaps the most interesting of all. It was shown, namely, that portions of the very same fluids which had produced the most fatal forms of lung inflammation might, on the admixture of a little iodoform with them, be injected with safety into the trachea, the animal appearing to suffer no ill effects from the experiment. These observations of Woelfler and Paneth, conducted with great care, are in many respects confirmed by other observers. They appear to support the conclusions already arrived at from clinical and pathological study on the human being in many important particulars; and, above all, they indicate a means of escape from the terrible dangers of operations on the tongue. We shall see presently that the introduction of iodoform as a dressing for wounds after operation on the mouth has been followed by a great improvement in the results and diminution of the risks of septic lung complications.

How these risks are to be avoided has already been generally considered in speaking of the various excisions of the tongue. But in this direction much remains to be done. For if, in the future, more radical operations on the diseased and surrounding parts than have hitherto been generally in use be demanded for the thorough eradication of epithelioma, as I think will appear from what has been shown above (p. 604), then it must be one of our greatest aims to eliminate this terrible risk of lung complication from direct or indirect infection which has been bound up with the severer operations hitherto. Much has, to be sure, been done lately in this direction, but much more remains still to be done. The true interests of those suffering from cancer of the tongue will not be best served by adopting as our routine practice those modes of extirpation with small immediate risks, but which may be demonstrated to be wholly inadequate to prevent the disease from spreading. We shall have done our best for them only when we have taught ourselves which is the operation most calculated to secure the patient against recurrence of an otherwise inevitably and rapidly fatal disease, and when we have reduced the immediate risks of this operation to a minimum. That the radical operations will eventually be rendered far less dangerous than they are at present we have every warrant for believing from the improvement which has already taken place. And that the direction in which this advance is to be further made will be in the perfecting of antiseptic methods of operating, and of after treatment suitable to wounds of the mouth and the neck, is plain from a study of the facts before us. Kocher's series of 14 cases, with 4 radical cures with no recurrence after 1 year and 2 months, 5 years, 5 and 6 years respectively, and only 1 death, and the way in which he attained to these good results, point significantly in this direction.

Again, as an instance of what may be done in the direction of the after treatment of the wounded mouth, we may refer to our own last 18 cases of the University College Hospital tables (p. 585), of which only 2 died, or 11·1 per cent., the above dangers being now better recognised than in former years when the mortality was much higher. Again, to a series of 17 consecutive cases just published by Woelfler,¹ from the Klinik of Professor Billroth. Of these 17, it is to be noted that not only has none died, but there has been a total absence of all those local or general complications which have been the cause of such a high mortality in the tongue operations, in the same Klinik hitherto. Apparently this improvement is entirely due to the mode of dressing employed for the after treatment of the wounds; for most of the operations in the series have been performed by a method which, as will be seen by reference to von Winniwarther's tables below (p. 617), gave a very high mortality in former years. Out of this series of 17 cases, 13 were extirpations from the mouth, with preliminary ligature of the lingual artery, and there were no deaths;

¹ Woelfler, 'Zur Wundbehandl. im Munde,' *Archiv f. klin. Chir.* Bd. xxvii. p. 419.

whereas in von Winniwarter's table the same operation in 18 cases showed 27·7 per cent. The treatment followed by such excellent results has the merit of extreme simplicity among others. It consists in packing the hollow wound resulting from the removal of the whole or part of the tongue with iodoform gauze, which forms a dressing which moulds itself to all the corners of the cavity, and there 'cakes.' The mass thus formed over the wound adheres to the latter for several days, and cannot be removed without giving rise to bleeding. It is therefore left *in situ* until loosened by the granulation of the underlying surface, which is usually on about the 6th or 8th day. When it comes away the wound is found quite clean, and retains enough of the iodoform on its surface to keep it so until it is healed. This treatment appears to promise much, modified or not as the case may be. I have only had an opportunity of employing it once in a case still under treatment, on which I operated a month ago. But, as far as this case was concerned, the mouth remained perfectly sweet throughout, and the only disadvantage the dressing appeared to have was probably due to my putting too much iodoform on the gauze. The patient appeared to suffer a little from it, and to feel nauseated for a day or two. But this may not have been due, of course, to the drug. In other cases, in which my colleague, Mr. Heath, has used powdered iodoform as a simple dressing without gauze for the wound at the base of the tongue, the results have been equally good. Indeed, it would appear from recent observations that in this strong antiseptic we have discovered the best dressing yet used for the after treatment of excisions of the tongue and floor of the mouth. This will no doubt be employed in various ways, according to the fancy of different surgeons, but if it continue to give as good results as heretofore in preventing septic changes in the secretions on the wound surfaces, but little is left to be desired.

In most of the cases in the series just alluded to, the patients were fed by an œsophageal tube introduced for each meal for several days, and there can be little doubt that this contributed to some extent towards the very good results obtained, the mouth being thus kept quiet and much cleaner than could otherwise be expected.

In several of the cases at University College Hospital we have adopted the plan of feeding our patients with nutritive enemata for the first few days, with a similar object in view, and this has answered well as long as the rectum tolerates the injections. As a rule this is only for a few days, after which it becomes very irritable and expels even small enemata. But in the meantime the wound has probably reached the stage of clean granulation, after which there is less danger of the particles of food sticking in corners of the cavity and provoking foulness. Other surgeons have found this plan to answer equally well.

Washes of various kinds may also be used with some benefit after excision of the tongue, though not equal as antiseptics to applications of Iodoform. Among these Chlorate and Permanganate of Potash, or Carbolic Acid, are perhaps the best, but they often produce severe pain in the wounded part, and the very necessity of constant repetition places them much behind iodoform as a dressing, which requires to be renewed only once or twice in a day. Crystals of Permanganate of Potash have also been used to apply to the wounded surfaces at the first dressing as an escharotic, which was hoped would prevent septic absorption, but it has fallen again into disuse, iodoform dressing replacing it.

Relative mortality of different operations.—A glance at the relative mortality of the various methods of extirpation already enumerated may perhaps now suitably follow the above table. But here we are met by the great difficulty of classifying the published operations, so few of these are precisely alike, owing to the individual peculiarities of each case and the particular fancy of the various surgeons who have dealt with them. They may be, however, roughly classed in two ways; but we must be on our guard against placing too much reliance upon the hard figures brought out under either mode. Thus they may be arranged—(1) according to the position from which the tongue was removed, and (2) according to the appliance used for the actual severance of the tissues. In the first case the tongue will have been partially or wholly extirpated either (a) through the mouth; (b) after division of the jaw; or (c) from beneath the

latter. In the second case, either (a) the wire or chain *écraseur* has been used, or (b) the galvanic *écraseur*, or (c) the simple cutting instruments, knives, or scissors.

In our table of 38 operations for cancer of tongue, the first classification will only go a short way, the great majority of the tongues having been removed through the mouth. But all the more it is of value as showing the relative dangers of the galvanic and the simple *écraseur* to some extent, though the numbers are small. The operations arrange themselves as follows:—

	Total	Died	Mortality, p.c.
Galv. <i>écraseur</i> from the mouth .	13	5	38·4
" after division of jaw	4	3	75·0
Wire <i>écraseur</i> from the mouth .	12	1	8·3
" from hyoid incision	5	1	20·0
Scissors from mouth	2	—	
Knife and cautery from mouth .	1	—	
Knife after division of jaw . .	1	—	
	38	10	26·3

Thus it will be seen that out of 17 cases where the galv. *écraseur* was used, 8 died, 6 of the deaths being due to the direct lung affections described above, the remaining 2 dying respectively of *œdema glottidis* and ordinary *septicæmia*. Of 17 cases in which the wire *écraseur* was employed, 2 died, one of surgical pneumonia the other of ordinary *pyæmia*, with abscesses over the spleen and renal infarcts, the lungs being healthy.

Billroth's two series of cases are classified in somewhat the same way as above, except that there are two additions not represented among our cases and that operations for recurrence are included. The latter fact of course lowers the mortality relatively, for in this country second operations are not usually counted in this way in statistics. In examining the table below, it must be remembered that the first series (von Winniwarter) includes only 42 patients, and the second (Woelfler) 44. The statistics, however, are particularly valuable as coming from the experience of one operator and his assistants in one hospital:—

	VON WINNIWARTER			WOELFLER			Mortality total of combined tables
	Total	Died	Mortality	Total	Died	Mortality	
Extirpation from the mouth, including 7 (von W.'s table) by galvanic <i>écraseur</i>	21	2	9·5	20	5	25·0	17·0
Extirpation from the mouth after ligature of lingual artery or arteries	18	5	27·7	20	2	10·0	18·4
Extirpation from supra-hyoid region	13	6	46·1	4	—	—	35·2
Extirpation with section of jaw; (1) 'temporary resection'; (2) removal of part of jaw	2	2	100	6	1	16·6	37·5
Total . . .	54	15	27·7	50	8	16·0	22·1
Extirpation of glands for recurrence	3	1	—	—	—	—	—
Extirpation of tongue by pharyngotomy incision	—	—	—	1	1	—	—
Total . . .	57	16	28·0	51	9	17·6	23·1 ¹

On carefully examining von Winniwarter's series of cases in detail, I find that they cannot be fairly compared with ours in any other way except in one point—namely,

¹ Or 29·0 on 80 individuals.

the excision by the galv. écraseur from the mouth. Of these there were 7, of which 2 died, or 28·5 per cent., results not quite so bad as where this instrument was used at our hospital in a larger number of cases, but still pointing to the risks attending on its employment. Apparently the wire or chain écraseur was not used in any of Billroth's cases, so that we have no way of contrasting his with ours in respect to the desirability of its employment. It may be mentioned further that in Woelfler's series where extirpation took place from the mouth, as in the first group of the above table without preliminary ligation of the lingual artery, the parts were cut in a large proportion of cases with a curved scissors by a method since independently advocated by Mr. Whitehead as possessing many advantages.

But one point is quite clear from all these analyses—namely, that though those operations for well-marked disease on the tongue which require extensive dissection along the floor of the mouth and side of the neck, with or without division of the jaw, have hitherto been the most dangerous of any, they have given the best results (where the patient has survived) as to non-recurrence or length of immunity from recurrence. And when we come to inquire into the nature of the risks connected with these more extensive operations we find them nearly all of one class—they are almost always due, namely, to septic infection of one kind or another. When the diseased tongue has been removed by the sub-maxillary method at its base, the dangers of shock of hæmorrhage into the air-passages or otherwise have not been encountered. The deaths resulting have in almost every instance been due to septicæmia, pyæmia, or surgical pneumonia. This being so, we may hope that the day will soon come when, having learned how to operate on this particular region aseptically, and in the after treatment to guard against putrid infection, we may proceed fearlessly to the more deliberate radical extirpation of the diseased tongue and infiltrated parts around, and so save our patients from recurrence, which so frequently follows the other methods that they almost deserve the name of the palliative operations. Such an elimination of the dangers of sepsis has gradually taken place in the history of other grave procedures of late years, thanks to the teaching of Mr. Lister in particular, and also to a general advance of surgery all along the line. And it is not too much to hope that it is quite possible here too. We now know our enemy and his various modes of attack in great measure. If we can meet him and foil him, we shall have achieved another triumph in surgery. We shall have rescued a large and possibly increasing class of patients from one of the most painful, distressing, and rapidly fatal forms of cancerous disease known. That we are justified in risking a good deal in the meantime in the pursuit of such an end, no one familiar with the history of these cases can for a moment doubt. The fact of the disease being so inevitably and rapidly fatal is enough for this. And we are further justified, after a considerable number of years' experience, by the knowledge that we have already achieved much, however much still remains to be done. That there is a great and useful future for the more extensive and radical operations on the tongue and the parts about its root, we may venture now to predict with confidence.

Palliative treatment for cancer of the tongue.—And though this be all true, it in no way lessens the force of the conclusion ventured on at the commencement of this section—namely, that the greatest of all advances in the treatment of cancer of the tongue is to be made in the direction of early diagnosis and early and decided operative interference while the disease is still purely and beyond all doubt local.

There now remain but a few words to be said as to the palliative treatment of cancer of the tongue, when, for any reason, excision of the organ is not undertaken.

The first great evil which the patient will wish to be relieved from will be the pain, which in many cases is almost intolerable. This is not present in every case of the affection, however, of cancer of the tongue; and I have seen cases in which even advanced disease produced but little discomfort. Still, the instances in which it is present, and they are many, call for relief urgently. The pain is usually felt, not only in the organ itself, but also frequently over nearly the whole distribution of the fifth nerve on the affected side. In such a case, anodynes will give only partial and temporary relief, and something more must be done. Here the division of the gustatory

nerve, proposed many years ago by Hilton, has been found of much benefit by several surgeons. The mode of performing this operation, defined later by Moore,¹ is perhaps better than that originally practised by Hilton, and is now usually followed. A curved bistoury is passed through the mucous membrane of the floor of the mouth, at a point corresponding to and in the direction of a line drawn from the last molar tooth to the angle of the jaw, and when it has reached below the ridge of the bone which corresponds to the nerve, it is pressed firmly outwards against the jaw and made to cut upon the latter as it is withdrawn. In this way the nerve is severed as far back as is necessary. In Moore's cases the relief to the pain was great and lasting, and the patient's condition was much improved.

This operation has another good effect, hardly less marked—namely, an arrest of the profuse salivation which in many cases renders a patient's life very miserable, and is besides very exhausting.

The next trouble which will call for treatment will be the intense fœtor arising from the decomposing debris of the ulcer with the saliva secreted over it. This is often acutely distressing to the patient and his friends, and may lead eventually to surgical pneumonia if not checked, as in two of Moore's cases. This is best treated by the sprinkling over the ulcerated surface, cleaned previously as far as possible, of a small quantity of powdered iodoform. If the growth have been fairly dried beforehand, this will cling and stick to the surface for a long time, even days, and most effectually control all decomposition, as I have seen in more than one case. If this be not to hand, washes of Couley's fluid, of Chlorate of Potash, or Carbolic Acid in solution may be used with good effect. But these are troublesome from the necessity of constant repetition, and often from the aggravation of the pain which they often produce. The introduction of Iodoform into the treatment of such cases has therefore been a great advance, for there is no objection to its use if not too freely applied, and its effect is slightly anodyne as well as strongly antiseptic.

Again patients with advanced lingual cancer not unfrequently suffer from repeated bleedings from opening up of the arteries of the tongue. Here we are frequently driven from one strong local hæmostatic to another, until at last ligature of the lingual artery has to be resorted to. This will generally be effectual, but is by no means an easy operation if, as is usual in advanced cases, the side of the neck be the seat of much induration around infiltrated glands. Hence an extra reason, if one were wanting, for the performance of early excision. For we know that in the vast majority of cases the disease once removed from the tongue and floor of the mouth does not recur there again, but in the glands, and thus the risks of hæmorrhage are eliminated in the further course of the case.

Finally, the pressure effects of the recurrent growths in the neck may have to be considered. Thus we may be called upon to feed a patient with a catheter passed down the œsophagus past an obstruction from enlarged glands, as in one of our latest cases at University College Hospital; or the question of the propriety of gastrotomy may have to be entertained if this fail. But these are matters of general surgery, and need not be more than alluded to here.

In conclusion, it may be well to recall the fact once more that extirpation of the tongue for cancer removes several of these sources of distress just alluded to, to which patients unoperated on are almost inevitably exposed—namely, pain, fœtor, salivation, and the swallowing of discharges, and life is thus rendered at least tolerable, if it is not prolonged.

ARTHUR E. BARKER.

DIPHTHERIA AND CROUP.

DIPHTHERIA.

A FEW years ago the name of diphtheria was unknown in England. It is highly probable that the descriptions of some of our older writers refer to this disease, which no doubt appeared then, as now, in an epidemic form; but for a very long period England had been free from its presence, and our acquaintance with its symptoms and consequences was, till recently, chiefly derived from observations made in France, where it had been known and studied for a number of years.

The first observations which, in this country at least, led to a true understanding of the nature of that false membrane which so eminently characterises diphtheria were made with reference to sporadic croup by Dr. Home,¹ about the middle of the last century. He first recognised the existence of a mass of fibrine, moulded to the form of the subjacent structures, and adherent to the mucous membrane, but lying quite upon its surface, 'and generally lying loose upon it.' Prior to this date such exudations were supposed to be part of the membrane itself, detached in the form of a slough.

In 1801 Dr. Cheyne published his essay on 'Cynanche Trachealis, or Croup,' in which he described clearly a membranous laryngitis, and figured the post-mortem appearance of the parts concerned.

From this time the word 'croup' began to be applied to that form of inflammation of the air-passages which is attended with the production of a false membrane.

In 1821 Bretonneau,² in his *Memoirs* read before the French Academy, called attention to an epidemic disease, in which occurred a specific inflammation attended with the formation of false membrane, chiefly upon the mucous membrane of the throat and windpipe, but also upon excoriated skin. This disease he called first 'diphtherite' and subsequently 'diphtherie'; he considered it due to a specific virus, and believed that membranous croup was one of its manifestations.

Thus arose the name 'diphtheria,' which has ever since been employed to designate the disease of which Bretonneau gave the first scientific account, the symptoms of which have undergone so little change, that his report continues to be a very faithful picture of the usual forms which it presents, although his theory of the local character of the disease has been now almost entirely abandoned.

*Definition.*³—Diphtheria may therefore be defined as an acute specific febrile disease, contagious and often epidemic, the special characters of which are—(a) the formation of false membrane, chiefly upon the mucous membrane of the throat and air-passages, but also upon excoriated skin surfaces; (b) a grave and rapidly increasing depression and anæmia; and (c) in the later stages, evidences of disturbed innervation.

It attacks persons of all ages, but prevails most among children under seven years of age. Of adults, those are most prone to diphtheria who are suffering or convalescing from other diseases or from injury. Among children it is not uncommonly associated with measles, and with enteric and scarlet fevers. It shows no preference for either sex.

¹ *An Inquiry into the Nature, Causes, and Cure of the Croup*, by Francis Home, M.D.

² *Memoirs on Diphtheria*, published by the New Sydenham Society.

³ For definition of the word 'diphtheria,' the reader is also referred to the 'Report of the Scientific Committee' of the Medico-Chirurgical Society, 'On the Relations of Membranous Croup and Diphtheria,' *Med.-Chir. Trans.* vol. lxii. p. 30. Frequent use of this most valuable Report has been made in this article.

The most common source of the disease is doubtless contagion, and as with other inoculable diseases which are also certainly conveyed from the sick to the healthy through the atmosphere without actual contact, so with this there seems every reason to believe that in certain investigated instances the infection has been so propagated; and we can hardly withhold our assent to the proposition that it may be so in all, although it is not always, perhaps not often, possible to trace the source of the infection, and the means of its transmission.¹ Filth and bad drainage are, however, certainly favourable for its development.

Symptoms.—The incubation period of diphtheria is not certainly known; it appears to vary between a few hours and a week. At a variable period then, but usually a few days after exposure to the poison, the person attacked shows signs of general illness and febrile disturbance, accompanied usually by sore-throat, and often by some tenderness of the lymphatic glands at the angle of the jaw.

Diphtheritic fever.—The primary action of the poison when imbibed into the system is an alteration in the character of the blood. This we infer, in the first place, from the sense of malaise, and the febrile action, which, in some instances very slight indeed, but in some very severe, can be traced before any local manifestation occurs. This fever alone may kill, and when it does so, it is always by its assuming an asthenic character; the patient either becomes daily weaker, and ultimately dies of exhaustion, or the case is marked by a low muttering delirium, with a tendency to slough about the inflamed mucous membrane, excessive prostration, and rapid sinking; in either case the pulse is feeble and very frequent. It is to be borne in mind that this is the invariable character of the disease, however inflammatory the fever may in the first instance seem to be. In the second place, we infer the existence of blood-poisoning from the occasional appearance of purpura and sanious exudations in fatal cases, and the constant sequel of intense anaemia, even in comparatively mild cases, during convalescence.

These peculiarities are very striking, because the depression resulting from the attack is out of all proportion to its severity, and even when the fever is manifestly asthenic in its character, the subsequent weakness seems very much greater than might have been anticipated, and may end in a gradual but total failure of vital power after all danger had seemed to be at an end.

The fibrinous exudation.—The next immediate effect of the poison is the local action on the mucous membrane of the throat, which looks from the first swollen and red, as if it were the seat of active inflammation. And such no doubt it is; but it is a specific, and not an ordinary inflammation. It is quite different in its character and consequences from the ordinary inflammation of mucous membrane, and bears some analogy to that which is more commonly restricted to serous membrane; differing from it most, perhaps, in its tendency to localisation. We are all perfectly familiar with the rapid spread of the inflammatory blush, from a single point, over the whole involutions of the peritonæum, with its sticky, glazy, and fibrinous exudation; we see the same exudation forming a thick shreddy coating all over the heart or covering the entire surface of the pleura. In diphtheria we have the same character marking the exudation, but the parts involved are not coextensive with the limits of the membrane. In many cases the patches of lymph are few and small, and the inflammation is confined to the back of the throat. In a certain number of instances, the trachea, and even the bronchi, are involved; not unfrequently the membrane lining the nares is attacked more or less extensively; more rarely the exudation travels down the œsophagus; and in a few cases it reaches up the lachrymal duct to the surface of the eye. The laws of its extension seem to be much more in harmony with those of mucous than of serous inflammations, and there is but little difference in this respect between diphtheria and ordinary sore-throat, which may either be limited to the fauces, or may be the commencement of a catarrh ending in general bronchitis. The character of the exudation varies much in the same manner. When the extent of inflamed surface is small, the effusion is scanty, and the deposit of fibrine of less

¹ See Dr. W. Ogle's 'Remarks on the Dissemination of Diphtheria,' *St. George's Hospital Reports*, vol. ix. p. 704.

thickness and consistency; when the inflammation is more extensive, it is generally also more intense, and the effusion is thicker and denser, deeper and firmer. But there is no absolute rule in this respect. The fibrine is exactly analogous to that which usually covers inflamed serous membrane, presenting not only the same general appearances, but also the same microscopical elements.

The ordinary consistence of the effusion is such that it is often called false membrane; but it is sometimes scarcely more cohesive than paste, and contains more granular matter and cells than fibre in its structure. The mucous membrane on which it rests is almost always redder than usual; and when the fibrinous layer is removed, it looks raw and irritable, as if denuded of its epithelium; it is generally also dotted over with bloody points where the adhesion has been closer or the exudation has entered the mucous follicles and torn the tissue in its removal.

The diphtheritic exudation does not, however, always commence upon the throat; it may attack primarily the larynx, the nares, or the posterior surface of the soft palate, situations where its presence would be less obvious and where its discovery may be difficult. It may also be seen on the skin when the cuticle has been removed by a blister; and it is alleged that the contagion of the disease has spread in this way to persons who have had blisters applied while living in rooms where others have been suffering from diphtheria. Any ulcerated or abraded surface, in persons labouring under the disease, may similarly become coated with false membrane; and not unfrequently the mucous membrane of the pudenda in female children is the seat of a similar exudation. Suppuration of an unhealthy kind sometimes attacks the mucous membrane beneath the exudation, which melts away with a gangrenous odour, leaving a slough or a foul ulcerated surface behind; and then the whole course of the disease may be changed, and the patient may fall into that low typhoid condition which is believed to be caused by the absorption of unhealthy inflammatory products.

The mere fact of exudation having taken place, apart from its value as an indication of the severity of the attack, claims our most earnest attention, from its occasional bearing on the issue of the case as a local complication. It is not the extent of surface attacked which excites apprehension, but the importance to life of the narrow chink through which air is drawn into the lungs, and the readiness with which a very small amount of thickening, or a very slight deposit on the membrane covering the chordæ vocales, may obstruct the entrance of air, and cause death by suffocation. It would appear that in different epidemics the tendency of the inflammation to spread to the larynx has varied very greatly; sometimes a majority, sometimes but a small number of the deaths resulting from this circumstance.

There is no doubt, however, that the tendency to the laryngeal implication is in proportion to the youth of the patient, and the mortality may be said to have the same relation to age. The gravity of laryngeal diphtheria may be estimated by the statement of the Committee of the Medical Chirurgical Society that 'the mortality where laryngeal membrane is found, whether with or without faucial, is 90 per cent.'

The character of the symptoms will obviously depend to some extent upon the locality of the diphtheritic membrane. If the tonsils, palate, or pharynx be the part attacked, there will be painful deglutition, tenderness and swelling of the glands near the angle of the jaw, and perhaps deafness, or suppuration of the middle ear. Post-pharyngeal abscess also sometimes forms, and adds to the difficulty of swallowing. If the nares are the seat of the exudation, coryza and foul discharge from the nose will be present, while the laryngeal complication soon makes itself evident by rapidly increasing dyspnoea and all its attendant distress. When the laryngeal symptoms occur, they are of a gravity which at once makes them the prominent feature of the disease. The child becomes increasingly restless; the respiration stridulous, and the cough of metallic harshness; the voice becomes whispering or is lost altogether; there is an expression of great anxiety; the complexion becomes livid, and the pulse rapid and weak. An important symptom, indicative of the obstruction to the ingress of air to the lungs, is the recession of the soft parts of the chest with each inspiration; this is the more marked the greater the respiratory efforts. The urgency of the

symptoms may be temporarily relieved by the expectoration of false membrane; or aggravated by recurring spasm of the glottis. The difficulty of the breathing induces great exhaustion, and, as the disease progresses, the patient is less able to maintain the effort. The respiration becomes more shallow, the drowsiness more overpowering, and death occurs either in a sudden spasm of the glottis, or in a condition of coma or exhaustion. In the course of these events large portions of the lungs may become collapsed, or consolidation may occur from lobular pneumonia.

Albuminuria.—Another symptom of common occurrence in the severer forms of diphtheria is an albuminous state of the urine. As in scarlatina, the presence of albumen is simply due to congestion of the kidney; and we conclude that in some way or other the vitiated or poisoned blood stimulates the capillary vessels so as to produce this state of congestion; but we have as yet no clue to unravel further the mystery. In the one disease the urine presents no trace of albumen during the acute stage, the congestion only appearing with the desquamation of the cuticle after the febrile condition—the scarlet fever, so to speak—has passed off; in the other it commences at a very early period of the disease, generally lasts only for a few days, and does not cling to the patient during convalescence, as is the case so often in scarlatina. It causes no surprise that we cannot explain these peculiarities, since we have no idea why the complication exists at all, when it does not accompany any other form of sore-throat, nor to the same extent any other febrile disorder.

Paralysis. Another phenomenon accompanies or rather follows upon attacks of diphtheria with sufficient frequency to establish a certain relationship between them; but as yet we can only affirm that paralytic affections may be apprehended after partial convalescence from diphtheria—after, indeed, the throat is perfectly well, and nothing seems wanting to recovery but the due performance of the nutritive functions. This may be the gravest of the sequelæ, since patients may die of paralysis of the heart¹ when no lesion whatever can be traced after death. The paralysis most frequently affects only the muscles of deglutition and of speech, but does also sometimes include nearly all the muscular tissues throughout the body; the sight becomes impaired through loss of the adjusting power of the eye,² the pulse fails, apparently from diminished nervous energy in the heart, the legs and arms become partially powerless, and sensations of tingling and numbness are complained of, or actual anæsthesia exists.

Epidemics of diphtheria vary much in severity, and wherever the disease is prevalent there commonly occur a considerable number of cases of sore-throat, attended with an unusual amount of depression, and followed by anæmia, cases which it is fair to presume have their origin in a diluted or mild infection with the diphtheritic poison.³

Treatment. The fatal termination of an attack of diphtheria may follow either as a remote or immediate result of the fever itself, or in consequence of the obstruction of the larynx by local exudation; and the treatment must vary as the one or the other of these symptoms is the predominant feature of the case. Like the other acute specific diseases, diphtheria must be treated on general principles, inasmuch as no specific remedies have yet been discovered which have the power of destroying the blood-poisons on which they severally depend.

1. In some rare cases the patient is at once prostrated by the severity of the fever; he has a brown tongue, a quick and feeble pulse, probably purpurous spots on his body, or a sanious discharge from the nose or fauces, and occasionally muttering delirium. Such cases rarely show any signs of rallying; and the freest use of stimulants affords the only chance of saving the patient or enabling him to recover from the shock of the attack.

2. If not thus prostrate from the very first, yet generally from an early period the tendency of the disease is to assume a low or asthenic type, and to produce a depression, which must be met or even forestalled by the administration of stimulants. The difficulty of swallowing must not be permitted to interfere with the quantity of

¹ *Diphtheria, its Symptoms and Treatment*, by William Jenner, M.D.; pp. 42–59.⁴

² *Diphtheria*, by E. H. Greenhow, M.D., p. 220.

³ See also Dr. W. Ogle, *op. cit.* p. 702.

nourishment taken ; patients who escape the first severity of the disease are still exposed to the danger of a lingering convalescence, or a gradual exhaustion of the vital powers ; and hence the importance of a sustaining mode of treatment, and of the careful avoidance from the outset of all lowering measures. Chlorate of potash, hydrochloric acid, quinine, and muriated tincture of iron, are the constitutional remedies on which, according to the testimony of most writers, the greatest reliance is to be placed ; but if, as is often the case, there is much difficulty in their administration, it is to be remembered that food and stimulants are of more importance than physic.

3. The occurrence of unhealthy suppuration or of pyæmic symptoms gives of course increased gravity to the case, and calls for increased activity in the administration of stimulants and tonic remedies. Abscesses should be opened early and dressed with antiseptic applications. In such cases opium and quinine are sometimes very useful, and, indeed, the extent to which both opiates and stimulants are borne is often surprising.

4. The local disorder claims our attention more especially when it spreads towards the larynx and trachea. The idea that the extent of the exudation was the cause of the severity of the symptoms has been entirely abandoned, and with it that meddling activity which deemed it necessary to apply caustics or astringents several times a day to the throat. An abraded surface, whether of cuticle or of mucous membrane, is speedily covered with the diphtheritic exudation in the severer forms of the disease, even when no contact of parts is possible ; and it would seem perfect madness to apply an escharotic which tends to denude the adjacent membrane of its epithelium, and prepare it for the fibrinous exudation which is certain to take its place. The application must be astringent, not escharotic ; a stimulant to the diseased surface, not a destroyer of its vitality. The occasional sponging with a solution of the perchloride of iron, or a very dilute mineral acid, or a weak solution of lunar caustic ; the use of atomised fluids containing detergents or astringents, such as sulphurous acid, myrrh, or benzoin ; inhalations or gargles of a similar kind ; these may assist in preventing the spread of the exudation, or in stimulating the parts to a more healthy action ; but the power of such means is allowed on all hands to be very limited.

When the larynx is also involved in the exudation, dyspnoea and insufficient aëration of blood add very materially to the sufferings of the patient and the probability of a fatal termination ; and the question naturally presents itself whether any, and how much, benefit may be anticipated from the operation of tracheotomy. It is by no means easy to give in few words a definite answer to this inquiry, or to lay down rules which may be sufficient to guide the practitioner in deciding on his course. If we turn to statistics, we find that the fatal termination is not averted to any great extent, although in all probability some lives have been saved by the operation which must otherwise have been lost. But it is manifestly impossible to frame a series of cases in which it has not been performed, which shall be an exact counterpart to those operated upon ; and without such a basis of comparison, the knowledge of the exact number of deaths and recoveries after operation is valueless. It is indeed asserted that of late years the mortality in France after tracheotomy is not nearly so great as formerly ; but this may depend not so much on the results being more favourable, as on a more hopeful series of cases being selected. In such circumstances we must be guided by general principles, and the rules for our guidance must be admitted to be based partly on conjecture. It may be assumed then, first of all, with tolerable confidence, that when the general symptoms indicate that the attack is comparatively mild, while the danger of suffocation is imminent, tracheotomy does give a chance of life in cases otherwise all but hopeless, and that it certainly does give prompt and certain relief to the suffering immediately caused by dyspnoea, than which nothing is harder to bear. But no surgeon ought to undertake the operation, even in such circumstances, without fully explaining that relief, and relief only, from impending suffocation is its object. Secondly, when the dyspnoea is less intense, it becomes a question whether the relief to the breathing may not help forward the process of cure which nature is working out ; or it may rather be said,

whether the existing amount of dyspnoea does not materially hinder the recovery, and render it more uncertain. The French surgeons are disposed to answer in the affirmative; and the opinion is shared by many among ourselves; but the practice is clearly not one that can be urged as necessary in the present state of our knowledge. Thirdly, in the very severe forms of the disease, we may well pause before recommending the operation, because it is no longer a question of the possible saving of life, but one merely of giving temporary relief. In addition to which, we must remember that the operation may entirely fail to give relief in consequence of the trachea and bronchi being blocked up by false membrane. In such cases it can only be justified by intense dyspnoea and impending suffocation, and by the earnest longing of the patient, or the friends, to have something done to procure relief. Could we know with any degree of certainty how far the exudation extended into the trachea and bronchial tubes, we should have most valuable information to guide our decision. Auscultation should with this view always be carefully practised; but it must be confessed that the determination is a matter of extreme difficulty, and one in which the most experienced stethoscopist may fail to elicit any accurate or trustworthy information. If, however, the operation is determined upon, it is vain to defer it until exhaustion is extreme, or the lungs are hopelessly damaged.

5. When the urgent symptoms are passed, convalescence will be aided by the administration of iron, and by the free admission of fresh air and sunshine. All active exertion must for a time be avoided, and only resumed gradually and with caution. Care in this respect is especially needful should there be any symptoms of paralysis.

6. During the prevalence of the epidemic many slight cases occur, which assume more or less its specific characters, and are marked by the presence of small shreds of lymph on the fauces. An ordinary sore-throat at such times does not follow its usual course, but without manifest exposure to infection is somehow assimilated to diphtheria. These generally require no special treatment, and will in all probability end in recovery without the aid of medicine. Such cases should, however, be removed into a pure air, and carefully protected from all depressing influences.

CROUP.

The word 'croup' has long been in use, both among the common people and by physicians, to signify an acute febrile disease of children, attended with difficult breathing due to obstruction of the windpipe. But the exact nature of the disease has not been well defined; for it has been observed that the symptoms special to the larynx may have varying and extremely different concomitants, and that in some instances they lead to a rapidly fatal end, while in others they terminate in speedy recovery. It has thus become manifest that the symptoms which gave rise to the word 'croup' may be a part of several distinct diseases, and the relation of the symptoms to the diseases has been a matter of much uncertainty. Therefore, as it is desirable that our terms should only imply as much as we know, it will be both convenient and reasonable to adopt the suggestion of the Committee of the Medico-Chirurgical Society,¹ 'that the term "croup" be henceforth used wholly as a clinical definition, implying laryngeal obstruction occurring with febrile symptoms in children.' Using the word in this sense, it will be found that cases of 'croup' are separable into two classes, distinguished by the presence or absence of false membrane, and that although this criterion may not always be available (that is to say, it may not always be possible to determine the existence or not of false membrane), yet that there are certain broad and important distinctions between the two groups of cases, which give to each of them a very different signification.

The distinctions between membranous and non-membranous croup are chiefly these: ² First, that the membranous is enormously more fatal than the non-membranous disease, so that, speaking generally, it may be said that nearly all of the first class

¹ See *Report of Med.-Chir. Committee, supra cit.* p. 28.

² *Op. cit.* p. 38.

die, and nearly all of the second class recover. Second, the membranous affection shows no preference for sex, but the non-membranous is much more common among male children. Third, the onset of the membranous form of croup is much less sudden than of the non-membranous; in the first class of cases the patient usually shows signs of considerable illness for a day or two before the commencement of the laryngeal symptoms, and in many of this class the croup is consecutive to membranous inflammation of the throat or other parts; in the second class the attack is apt to come on suddenly in the night, without any premonitory symptoms, or after only those of slight catarrh. Fourth, in the cases which recover, the duration of the membranous is greater than of the non-membranous disease. Fifth, non-membranous croup is apt to recur, which is not the case with the membranous form. Sixth, there is a much greater tendency to albuminuria in membranous than in non-membranous croup.

Of membranous croup, by far the most common cause is the contagion of diphtheria, although probably it may arise from foul air and water, or other unhealthy surroundings, and also in association with measles, scarlatina, and typhoid fever, 'independently of any ascertainable exposure to the special diphtheritic infection.'¹ It appears also that membranous inflammation of the air-passages may occasionally follow exposure to cold, and accidental injuries, such as the inhalation of steam, or the introduction of a foreign body into the larynx; but cases of this kind are so rare that they do not call for separate consideration. All that need be said therefore concerning membranous croup will be found in the preceding section upon 'Diphtheria.'

Non-membranous croup is a disease of childhood, and may be either inflammatory or spasmodic. This division into inflammatory and spasmodic croup is necessary for the separation of two groups of the non-membranous disease which have an entirely different origin; nevertheless it is needful to point out that with the inflammatory symptoms spasm may be combined and moreover play a prominent part; and, on the other hand, that the spasmodic affection may be attended with some degree of pyrexia.

With these explanations, then, as to the limits of the criteria, cases of croup may be classified as follows:—

Croup	{	Membranous	{	1. Due to diphtheritic contagion.	{	No contagion traceable.
					2. Due to foul air or other unhealthy surroundings.		
					3. Associated with certain specific fevers.		
					4. Following exposure to cold.		
					5. Following injuries.		
	{	Non-membranous .	.	{	1. Inflammatory—catarrhal.	{	Very rare.
					2. Spasmodic—nervous.		

Inflammatory non-membranous croup is a catarrhal affection of childhood, occurring chiefly in cold weather, and especially during the prevalence of east winds. Boys are more prone to it than girls, and a child who has once suffered from its attack is liable to a recurrence. It usually comes on in the night; the child may have gone to bed apparently well, or more commonly with some slight catarrhal symptoms, when, after a few hours of restless sleep, it wakes in a condition of acute fever, and with a hard dry cough which has a very peculiar sharp ringing sound dependent on the changes which, from the first, occur in the larynx and trachea. The sound of the cough is so remarkable, that when a child produces this brassy tone in coughing, the attendant is tempted to conclude, without further inquiry, that the disease is croup. There is very generally no difficulty in swallowing, any feeling of soreness of throat being confined to the windpipe, and not reaching the fauces. The

¹ *Med.-Chir. Report, op. cit.* p. 31.

breathing is always hurried, partly as a consequence of the febrile state, partly because air enters the lungs with difficulty. As the disease proceeds this difficulty increases, and the dyspnoea recurs in paroxysms, which become every hour more distressing. Such paroxysms often follow a fit of coughing, but occasionally come on without any apparent cause. These symptoms are due to inflammation of the larynx and trachea, the mucous membrane of which is swollen and vascular, and in the first stage of the disease dry; subsequently a more or less abundant secretion occurs of tenacious mucus, or muco-purulent fluid. Towards morning there will probably be some abatement of the symptoms, which, however, increase again with the approach of night; but after a day or two, if there be no complication, the severity of the attack usually diminishes, the fever passes, and the child is left somewhat weak and hoarse, but not otherwise ill. For some time, however, there will be a liability to a return of hoarseness after any unusual vocal effort, and to a croupy cough on exposure to cold.

The disease usually ends in recovery, but death may occur in one of the paroxysms of dyspnoea, owing to spasmodic closure of the glottis. Complications moreover may arise; for instance, in a rickety child serious collapse of the lung may occur; or the laryngeal and tracheal affection may pass on to bronchitis and lobular pneumonia, each with their attendant dangers, and a corresponding increase in the gravity of the case.

Treatment.—The first essential in the treatment of this disease is, that the patient be placed in a warm, moist atmosphere. For this purpose the bed should be surrounded with curtains, within which should be directed a jet of steam from a bronchitis kettle, or some similar apparatus. If the child is robust, a few leeches may be applied over the top of the sternum. Warm fomentations or poultices should be placed over the throat, and a warm bath may with advantage be given at the outset. The bowels should be cleared by a mercurial purge; and salines, antimony, and bromide of potassium administered. If the difficulty of breathing increase to a serious extent, great relief may be obtained by antimonial emetics. The antimony should then be given, not in small doses, but in sufficient quantity to produce vomiting, which may thus be provoked from time to time as seems necessary. Perhaps, if given with ipecacuanha, a smaller dose of antimony suffices. If there be much spasm, opium and hyoscyamus are to be recommended. It is of great importance to keep the bowels clear, and to administer only the most digestible food. The presence of undigested food in the stomach is very apt to aggravate the laryngeal spasm. We must not forget, however, that children are easily depressed, and that difficult breathing is in itself extremely exhausting; the character of the pulse and the general aspect of the child must therefore be carefully watched, and any signs of failing power noted and acted upon. The prolongation of extreme dyspnoea, or the recurrence of severe spasm of the glottis, would call for tracheotomy.

SPASMODIC CROUP, child-crowing, or laryngismus stridulus, depends upon a spasm of the glottis having its origin in some nervous irritation. It is usually but a part of a convulsive disorder affecting other muscles besides those of the larynx. It is especially common among rickety children, and among those that are teething or have been recently weaned. In those that are prone to its attacks, the spasm is especially liable to occur during the prevalence of catarrhal symptoms. The affection is characterised by the suddenness of its onset: a child may seem perfectly well, with the exception perhaps of a slight catarrh or some sign of rickets, when, without any warning, and frequently just as it wakes from sleep, it makes a long inspiration, attended with a loud crowing sound, and with much effort. As the sound comes to an end, the effort may cease, and the child soon be comfortable again; or, on the other hand, the face may become livid, the lips blue, and suffocation seem imminent. At last the spasm ceases, breathing again begins, the colour returns, and the child bursts into a cry and is soon itself again. Death may, however, occur during a spasm, and this has been known to happen at its first occurrence. The attack may be excited by cough, by crying, by a cold draught, or other eccentric

irritation. At the same time there is often adduction of the thumb, abduction of the great toe, or other spasmodic muscular contractions.

The *treatment* of this affection consists of the removal, when possible, of any source of nervous irritation ; and in attention to the particular diathesis in connection with which it occurs. Anti-spasmodic remedies, especially bromide of potassium and chloral, are of great use during the prevalence of the attacks. On the occurrence of a severe spasm, chloroform should be administered if available, or the child should be placed in a warm bath ; the mouth should be opened and the tongue pulled forward ; or the head should be thrown back and the chin raised : or, finally, if the spasm continues, an opening should be made in the trachea.

A. W. BARCLAY, 1870.

WARRINGTON HAWARD, 1882.

DISEASES OF THE NOSE.

I. AFFECTIONS OF THE EXTERNAL PARTS.

THE nose is especially liable to the various diseases of the skin which occur upon the face, and is very apt to be the part first attacked by morbid processes which eventually extend to the adjacent tissues.

Thus lupus is a disease which commonly commences upon the nose; but it is by no means confined to that situation, nor has it any special characters therein, excepting that, from the anatomical arrangement and prominence of the feature, its destructive results are peculiarly disfiguring.¹

Rodent ulcer and epithelioma when they attack the nose do not differ either in their manifestations or treatment from these diseases as seen upon other parts.² The various kinds of nævus are not unfrequently seen upon the nose, and should be treated as on other parts of the face.³ For the subcutaneous form I have found the operation of dissecting out the growth, after turning back the requisite flap of skin, excellently adapted for this situation, as it leaves only a linear scar which is scarcely noticeable.

Billroth describes and figures a remarkable case of arterio-venous angioma which followed a fall in which the nose was struck.⁴

The only disease of the skin which needs especial mention in connection with the nose is *acne rosacea*, for this affection, though not confined to the nose, leads in its advanced stage to a form of integumentary hypertrophy which is peculiar to the part. This differs from the other forms of acne in that the sebaceous follicles are not primarily affected. It commences as a red shining spot in which the capillaries of the skin are seen to be dilated and injected; there is no swelling, but usually a sense of irritation and heat is felt in the part, which is increased by stimulating food and changes of temperature. The tip, or one side of the nose is often the only part affected; but in some cases the greater part of the skin of the face presents an unnatural degree of redness, and numerous dilated and congested vessels are seen ramifying upon the surface, which give to the countenance under any excitement a dusky purple hue.

As the disease progresses, the sebaceous follicles usually, but not always, become involved; indurated tubercles form, over which the skin is of a livid purple, and which sometimes undergo slow suppuration; or there may be merely an increased secretion of sebaceous matter producing a greasy condition of the affected surface. This form of the disease may persist for years, and in women, who are much more prone to it than men, does not usually give rise to further changes.

In men, however, especially in those who have been addicted to over-feeding, an infiltration and hypertrophy of the cutis and sebaceous follicles often ensues ('acne hypertrophica' of some authors), which leads to the formation of the irregularly lobulated and pendulous masses which frequently disfigure the nose. These growths, sometimes incorrectly called 'lipomata nasi,' do not consist of fat, but are due to hypertrophy of the cutis vera and sebaceous follicles, with dilatation of the small veins; they are of firm texture, and usually of purple colour; some are sessile and wart-like, others more or less pendulous.

The severer forms of *acne rosacea* are commonly attributed to the intemperate use of alcohol, and doubtless this is one of the causes of the disease; but there are

¹ See therefore the article on DISEASES OF THE SKIN.

² See the article on ULCERS, vol. i. p. 153. ³ See the article on TUMOURS, vol. i. p. 270.

⁴ Billroth, *Clinical Surgery*. Translated by C. T. Dent, p. 86.

many cases, especially in women, in which there is no such association, and the origin of which is often obscure.

The affection is one of adult and declining life, and is often connected with dyspepsia and with uterine disturbance. Alcoholic intemperance is certainly the most potent factor in the production of the hypertrophic variety; but, although the abuse of stimulants is not confined to one sex, this form of the disease is almost entirely limited to old men.

Treatment.—In all cases of *acne rosacea* the general condition of the sufferer should be considered, and any irregularities of the digestive or uterine system should be corrected, and the needful abstinence enforced. Regular exercise out of doors; careful but not necessarily low diet, and thorough ablution, are to be recommended, together with such tonics, purges, or aids to digestion as may seem necessary.

For local treatment in the early stages, and when the sebaceous follicles are not notably affected, the red spots should be brushed over with a lotion of bichloride of mercury, of a strength of two or three grains to the ounce, or with strong acetic acid. The raised pimples and patches may be touched with acid nitrate of mercury, and the larger tubercles may be opened with a narrow-bladed knife and the contents expressed.

One of the most useful applications is sulphur in the form either of a soap or an ointment. Fifteen grains of the iodide of sulphur to an ounce of cerate is an appropriate form; all ointment should be applied at night and thoroughly washed off in the morning with oatmeal and hot water. Linear scarification followed by stimulating lotions has also been by some recommended. When the stage of warty and pendulous hypertrophy has been reached, the redundant tissue should be excised.

In operating, the growths may either be simply cut off one by one; or an incision may be made in the median line down to the cartilage, and the skin with its outgrowths dissected off on either side. Care must be taken not to cut through the cartilages. During the operation, the surgeon or his assistant should keep a finger in the nostril to serve as a guide. The bleeding which ensues may be readily checked by pressure or by the application of styptics. There is much less danger of erysipelas and other serious results than is commonly supposed. The exposed surface usually heals favourably under cooling and soothing applications. When cicatrization is complete, it is remarkable how little disfigurement remains. In some rare instances there has been recurrence of the growth after extirpation.

DEFORMITIES AND DEFICIENCIES.

The nose is liable to various deformities and deficiencies. Some of them are congenital; others result from accident or disease. Some are more or less perfectly remediable by operation; others are best concealed by masks or artificial noses, which are now made and adapted with great skill.

Entire absence of the nose, as a congenital condition, is extremely rare, but some instances are on record. In the case of a female infant under the care of M. Maisonneuve 'the nose was replaced by a plane surface merely pierced by two small holes.'¹

Such cases are irremediable by surgery. When the nose has been destroyed by accident or disease, much improvement may in some cases be obtained by plastic surgery. The degree of success attainable will depend chiefly upon the amount of bone and cartilage remaining to support the new tissue, and upon the healthiness of the adjacent skin.

When the ~~soft~~ parts only of the nose are wanting, plastic operations may be undertaken with very satisfactory results.²

Occlusion and contraction of the nostrils.—These deformities of the nose are sometimes congenital, but much more rarely so than corresponding conditions of the ear, the anus, or the vagina. In some instances the nostrils are more or less completely closed by membrane,³ in others by firm fibrous tissue, or by simple continuity of in-

¹ *Bulletin de Thérapeutique*, 1855, vol. xlix. p. 559; quoted by Holmes, *On the Surgical Treatment of Children's Diseases*, 2nd ed. p. 128.

² Richerand, *Nosographie chirurgicale*, 4th ed. tome ii. p. 122.

³ See the article on PLASTIC SURGERY.

tegument. In other cases again, one ala or both may be adherent to the septum, or even to the upper lip. All these deformities interfere with respiration, and prevent the infant from sucking uninterruptedly. The earlier therefore they are remedied by operation the better. In most instances a simple incision of sufficient extent carefully made through the obstructing membrane is all that is requisite. The opening must be kept patent by strips of lint or a short elastic cannula, until the cut surfaces are completely skinned over. Sometimes it may be desirable to excise a portion of the obstructing tissue. In cases in which there is no indication of the opening of the nostril, the adherent parts must be gradually and cautiously divided until the nasal fossa is reached. If free respiration is not materially interfered with, or if one nostril only is obstructed, the operation may be deferred for a time.

In a case under the care of Mr. T. Smith in the Hospital for Sick Children, the right nostril had been closed from birth. The corresponding ala was flat and unsightly. The child suffered from snuffling and snoring. The adherent surfaces were divided by the knife and the opening made was maintained during a period of three weeks by means of a portion of gum catheter. A good result was obtained.¹

Billroth² relates a case of atresia of the nostrils 'in a girl three years old, the result of a cicatricial contraction after variola. The cicatrices were cut out and the opening dilated by laminaria tents. India-rubber tubes were passed in, and ultimately the normal width of the nasal cavities was completely restored.' It was doubtful, however, whether recovery was permanent.

Fraenkel³ mentions three cases of congenital bony closure of the posterior nares—a very rare condition. Of the first of them he says, 'Emmert operated successfully on such a case in a boy seven years old, who had never from his birth been able to breathe through his nose, who was therefore as a nursing reared with great difficulty and who had, furthermore, often had suffocative attacks during sleep. No air ever came out of his nostrils, but mucus did, as well as a stream of tears when he cried. The closure was occasioned by a bony wall, covered on both sides with mucous membrane.

In the second case Luschka had the opportunity of examining the parts in a girl who died soon after birth; the closure was proved to be due to a bony plate developed apparently from the palate bones.

In the third case, which was sent to Fraenkel by D. J. Wolff, the posterior aperture of the right nostril only was similarly closed.

II. AFFECTIONS OF THE INTERNAL PARTS.

For the diagnosis of diseases affecting the interior of the nose, its cavities may be explored by various means, some of which are equally applicable for facilitating the necessary treatment.

Much may be learnt by exploration with the finger passed either into the anterior nostrils, or behind the soft palate up to the posterior nares.

This mode of examination may be used with great advantage if the patient is placed under an anæsthetic, when with a little management the greater part of the nostrils can be explored, and the position of a polypus or portion of necrosed bone often exactly determined.

Rhinoscopy.—The cavities of the nostrils may be inspected from the front either by direct or reflected light.

If the patient is placed facing the sunlight, and the tip of the nose is pressed upwards by the thumb, the nostrils will be dilated so as to bring a good deal of their cavity into view. But for more complete examination some kind of speculum is needful, and it is more convenient to reflect the light into the nostril by an appropriate mirror. When sunlight cannot be obtained, an Argand burner with a condensing lens can be substituted, or some of the various forms of the oxyhydrogen or

the electric light. The reflecting mirror can be fixed to a forehead-band or a spectacle-frame, or it may be held in the hand. The speculum is best made of bent wire, so that it covers as little as possible of the surface to be inspected; and it should be self-retaining, so that the operator has both his hands at liberty.

FIG. 140.

FIG. 141.

In order to inspect the nasal cavities from behind, the same general arrangements are necessary as for laryngoscopy. The patient is seated with his back to the light, his head is thrown well back, and his mouth opened as wide as possible in such a

A very useful form is that known as 'Fraenkel's Nasal Speculum' represented in fig. 140.

The blades being introduced, one into each nostril, they are separated by means of the screw which forms the handle of the instrument. The nostrils are thus widely dilated, and the instrument remains in position without extraneous support. It may be used in a similar manner for dilating one nostril only. Another dilator which I have found extremely convenient is that invented by Mr. Cresswell Baber¹ (see figs. 141, 142). It consists of two hooks of silvered wire (curved, as seen in fig. 141)

united by an elastic band, passing obliquely round the head, and provided behind with a buckle. Fig. 142 shows the mode of application of the speculum. The double-curved hook passes over the tip of the nose, which it draws upwards; whilst the other hook is inserted into the outer angle of the nasal aperture. The amount of dilatation can be regulated by tightening or loosening the elastic band by means of the buckle behind; and the hooks, being to a certain extent flexible, their curve can be altered to suit individual cases.

In some cases, as suggested by Czerniak,² a small oval mirror, mounted at an angle upon a long slender stem, may be used with great advantage. When such a mirror is introduced to a greater or less depth through the nostril, and properly illuminated, there may be seen reflected in it various parts which could not otherwise be brought into view.

¹ See *Brit. Med. Journal*, Jan. 8, 1881.

² Czerniak on the Laryngoscope (*Sydenham Soc. Transactions*), p. 38.

manner as to display the pharyngeal cavity to the fullest practicable extent. For this purpose the velum should be at rest and the tongue lie passively just within the lower teeth.

The surgeon, seated opposite, reflects the light from a frontal mirror in such a direction as to illuminate the pharynx; then, with a spatula held in the left hand he depresses the tongue, and with the right hand introduces the rhinoscopic mirror into the space between the posterior wall of the pharynx and the velum; by slight movements of the mirror reflections of various parts of the nares and pharynx will thus be obtained. The handles of the tongue-spatula and of the rhinoscopic mirror should be so bent that they do not interfere with the light when in use (see fig. 143). The smallest of the laryngoscopic mirrors, with the stem bent into a double curve, answers the purpose very well.

Under favourable circumstances the two superior meatuses may be inspected, and considerable portions of the mucous membrane covering the turbinated bones and the septum may be seen, the posterior surface of the velum can be examined, and if the mirror is turned towards one side, the lateral wall of the naso-pharyngeal cavity and the orifice of the Eustachian tube may be brought into view. But the difficulties

of posterior rhinoscopy are great, and it is rarely that the cavities may be inspected to the extent indicated; although this is theoretically possible in most cases, and has been actually accomplished in many. Nevertheless, persevering attempts should always be made in doubtful cases. Experience has amply proved that this

method of examination, even when incompletely carried out, may afford most valuable aid, not only in the diagnosis, but also in the treatment of various affections of the nasal cavities. To insure success, considerable practice on the part of the surgeon, and oftentimes great patience and self-control on the part of the patient, are requisite.

The principal difficulties are due to the size or want of control of the tongue, to the sensitiveness of the soft palate, and to the tendency of the velum to become raised, stretched, and approximated closely to the posterior wall of the pharynx.

The tongue is best controlled by firm and even pressure by a spatula laid flat upon it and held steadily in one position; sometimes this is best done by the patient himself. The sensitiveness of the palate may be to some extent diminished by sucking ice immediately before the examination; and the retraction of the soft palate may be overcome in many cases by practice on the part of the patient in breathing through the nose as though snoring.

It is far better, if possible, to avoid the use of hooks or other instruments for drawing forward the velum; but occasionally the examination cannot be accomplished without such aid; when this is the case the velum may be lifted and drawn forward by a blunt hook, a thread noose, or by a little moveable spatula fixed to the handle of the rhinoscope (see fig. 143).

FIG. 143.—Rhinoscope, with uvula-holder (Frænkel).

NASAL CALCULI. RHINOLITHES.

Calculus concretions are sometimes formed in the nasal cavities. Instances are rare, but a considerable number have been placed on record.

Cloquet¹ relates several examples, and others are quoted or referred to by Demarquay in his elaborate memoir on the subject.² Cæsar Hawkins³ mentions a case in which

¹ Cloquet, *Ophthéologie*, p. 627. ² *Archives générales de Médecine*, 4^e série, vol. viii. p. 174.

³ Cæsar Hawkins, *Contributions to Pathology and Surgery*, vol. i. p. 235.

concretions, exactly the shape of the superior spongy bone, used to come away from time to time either by the nostril or from the throat of a delicate person subject to hæmoptysis. The same author alludes also to an instance in which both nostrils were obstructed by chalky bodies, which, with the accompanying inflammation and swelling, produced an appearance resembling that of a malignant polypus.

These concretions are, for the most part, met with in the inferior meatus, and the majority are formed around some foreign body which has been retained in the nose. Sometimes, however, the nucleus appears to be simply inspissated mucus.

These calculi consist (according to the analyses of Bouchardat) of the phosphates and carbonates of lime and magnesia, chloride of sodium, and mucus or some other animal matter.

The ordinary symptoms of the presence of a foreign body or calculus are dryness of the affected nostril, accompanied by a sense of weight and fullness; frequently more or less obstruction of respiration; pain of an intermittent neuralgic character referred to the nose or forehead; and sometimes inflammation, and swelling of the adjacent parts, with copious discharge of mucus and pus from the nares. The sense of smell may be impaired or abolished. The eye may suffer discomfort also from the obstruction of the nasal duct.

Sometimes it will be possible to obtain a history of the introduction of some foreign body into the nostril, a not uncommon occurrence with children. The diagnosis can usually be made certain by the use of a probe or by rhinoscopic inspection; but it must be remembered that the mucous membrane of the nose has been known to undergo calcareous degeneration, a condition which might be mistaken for a calculous formation.

Treatment.—The treatment will consist in removing the concretion or foreign body, and thoroughly washing out the cavities by means of the nasal douche. It is of course important to ascertain certainly the presence and situation of the body to be removed, and it may not be out of place to point out that a thorough examination of the nose should be made before any such operation is attempted; for in children, though there may be a clear history of the introduction of a foreign body, it may have fallen out or have been swallowed without the knowledge of the patient; and it has happened to myself to find and extract a foreign body from the *right* nostril, when the mother of the child (an intelligent person) insisted positively that it was in the *left*.

The patient should be placed as for anterior rhinoscopy, and a good light reflected into the nose from a frontal mirror. The most convenient instruments to use are thin-bladed dressing-forceps and small scoops. But care is requisite in seizing the calculus, otherwise the pressure of the instrument may only serve to push it more deeply into the cavity. Forceps made in two distinct portions, which can be introduced separately and afterwards locked together, are very useful for the purpose. After the extraction of a foreign body, all that is usually needful is the washing out of any secretion which collects in the nose with a soothing lotion.

When there is a tendency to the formation of calculi, it will probably be found that there is some constitutional disease requiring correction. In one case related by Mr. Caesar Hawkins much benefit was derived from the administration of arsenic and sarsaparilla. Graefe considers that the gouty dyscrasia favours the production of nasal calculi; any symptoms of this disease therefore, or of syphilis or scrofula, should meet with appropriate general treatment. The local applications to be used after the removal of the calculus should be such as are adapted to cleansing the nasal cavities, and correcting any unhealthy condition of the lining membrane; weak alkaline solutions, diluted glycerine, and solution of permanganate of potash, are among the most useful.

EPISTAXIS. BLEEDING FROM THE NOSE.

The mucous membrane of the nose is very vascular: its blood-vessels are numerous, though none of them are very large; they are derived from many different sources, and they anastomose very freely; they form, especially in the young, impor-

tant media of communication between the vessels within the cranium and those which are distributed externally; the tissues which support them are in close relation with bone or cartilage, and are subject to injuries, abrasions, and ulcerations; and the vessels themselves are liable to become distended and congested from various different causes. Hence it happens that bleeding from the nose is of very frequent occurrence. In a large proportion of cases such bleeding is of trifling importance, in some cases it seems to afford relief, and to be really beneficial. Sometimes, however, it is symptomatic of visceral disease, or of degeneration of blood. Occasionally, if unchecked, or if frequently recurrent, it may prove serious, dangerous, or even fatal. The blood usually escapes from the nose drop by drop, but sometimes it flows in a fine stream. As a rule it comes from one nostril only, rarely from both simultaneously.

Epistaxis may be 'accidental' or 'spontaneous' in origin.

Accidental epistaxis resulting from a blow upon the nose, with or without fracture of the bones, is very common. In some boys it may be brought on by a very slight blow, or by any unusual exertion, or even by sneezing, or blowing the nose violently, it rarely goes on to a serious extent.

Spontaneous epistaxis arises from many different causes. It may occur as capillary hæmorrhage consequent upon either active or passive congestion; or it may result from ulceration extending into some one or other of the larger vessels, or it may be associated with, and indicative of, the presence of a polypoid growth.

The spontaneous epistaxis so frequently met with among young people of nervous temperament and delicate skin, is one of the most common forms of capillary hæmorrhage. It is usually preceded by active congestion, which is sometimes associated with over-fulness of the intracranial vessels, and accompanied by flushing of the face, buzzing in the ears, and a sense of heaviness or even severe headache. These symptoms are commonly relieved by the bleeding.

In young women capillary hæmorrhage from the nose is occasionally vicarious of suppressed menstrual flow, and under such circumstances may be considered salutary.

Bleeding from the nose frequently occurs in scurvy, and fever, and in other affections associated with an impoverished state of the blood. In persons of hæmorrhagic diathesis it often becomes a source of great anxiety and difficulty.

The epistaxis of declining or advanced life should never be lightly regarded. It is usually preceded by mechanical or passive congestion, which may result from over-distension or obstruction of the vessels conveying the blood from the brain, or may betoken the existence of some visceral disease of more or less serious character. The blood that flows is often venous in appearance.

Treatment.—In the treatment of epistaxis discrimination and judgment on the part of the surgeon are demanded as frequently as promptitude and skill. It is one thing to devise and apply the best means for the immediate arrest of the hæmorrhage; it is another to decide whether or not it is better to make the attempt. In very many cases the conditions which have given rise to the bleeding require treatment, rather than the incidental and temporary flow of blood which indicates the existence of such conditions. In some instances the non-recurrence of periodical or habitual epistaxis may betoken the approach of danger; and in others the sudden arrest of the bleeding by surgical interference may be followed by symptoms of the gravest import.

Accidental epistaxis may usually be arrested by the simplest means. So also, as a general rule, may the spontaneous capillary epistaxis of early life. Cold applications to the nose and forehead, snuffing cold water up the nose, the introduction of a piece of ice into the nostril, and such-like remedies are generally efficacious. The nursery remedy of slipping a cold key down the back, or far better of suddenly dashing cold water over the spine, seems sometimes to answer almost magically;—possibly, as has been suggested, through some reflex action excited in the vaso-motor nervous system. In some cases the vertical elevation of the arms as high as possible above the head, is successful.

Another simple and often effectual method consists in firmly compressing the alæ of the affected side against the septum, and pressure may sometimes be made upon

the bleeding point by a finger introduced into the nostril. The patient should be kept quiet and cool; and should sit upright with the head very slightly inclined forwards, so that if there be any bleeding the blood may find its way out of the anterior nostrils and not into the pharynx.

If these means are insufficient for the arrest of the bleeding, a stream of iced water or of some astringent solution should be passed through the nostril by the nasal douche. Or astringents, such as the solution of perchloride of iron, may be applied to the interior of the nostril by a pair of curved forceps, around the blades of which is wrapped a piece of lint saturated with the astringent.

On the failure of such measures as have been described there remains the expedient of plugging the anterior and posterior nares. This, though unpleasant to the patient, and not always easy to the surgeon, is so certainly efficacious, that it should never be delayed when the loss of blood has been dangerous. The best apparatus for this purpose with which I am acquainted is the inflating nasal plug invented by Mr. H. C. Howard. 'It consists of an india-rubber bag of the length of the nostril, compressed in the middle, so that the two enlarged ends plug respectively the anterior and posterior nares. The narrowing in the middle is made for the purpose of allowing the pressure to be as little as possible on the inferior turbinated bone. It is passed into the nose by a probe hitched on the under side. To the anterior extremity is attached a tube with stopcock, by which the plug is inflated.'¹ To remove the plug it is only necessary to allow the air to escape by turning the stopcock, when by pulling on the tube it is easily withdrawn. The advantages of this instrument are its easy introduction and withdrawal, and its cleanliness.

The operation of plugging the nares may also be accomplished by means of Belloc's sound. This consists of a silver cannula (slightly curved at the distal end, and six or eight inches in length), within which freely slides a stylet some four or five inches longer than the cannula. The proximal portion of the stylet is rigid to an extent corresponding in length to the straight portion of the cannula. Its distal portion is made of a piece of 'mainspring' which tends to curve round in the proper direction, and is terminated by a perforated button. The operation is performed as follows:—The eye of the button is threaded with a long piece of strong silk, and the stylet is drawn up until the button lies against the end of the cannula. The instrument thus armed is passed along the floor of the nose into the pharynx. The stylet is then pushed along the cannula, and the spring turns round the posterior border of the velum into the mouth. The silk is seized and drawn out through the mouth, and a portion of sponge of sufficient size to fill the naso-pharyngeal opening somewhat tightly is attached to it. The instrument is next withdrawn, carrying with it through the nostril the other end of the silk. By means of traction upon the silk and manipulation with the finger, the piece of sponge is then fitted into the naso-pharyngeal opening in such a manner as to block it up completely. Lastly, a second plug of lint or sponge is attached to the other end of the silk, and firmly fitted into the nostril. It is obvious that this operation may be accomplished as effectually, though perhaps not so easily, by various other instruments, as, for example, a long bent probe, the stripped feather portion of a quill, or a gum-elastic catheter. The last-named instrument, properly threaded throughout its length and carrying a loop of silk hanging through its eye, answers extremely well. The plugs should not be allowed to remain more than about forty-eight hours, for they are necessarily a source of discomfort and irritation, and are liable to give rise to the formation of matter, which may speedily become offensive, and possibly poison the system. Professor Gross¹ says: 'I have seen several cases where from this cause the patient lost his life, being seized with a low form of fever, attended with delirium, which nothing could arrest. In one of the cases there were marked symptoms of pyæmia.' The plugs may be easily removed by cutting the silk which connects them, withdrawing the anterior plug from the nostril, and pushing the posterior one into the pharynx, where it is caught by a spoon or a pair of forceps; or

¹ See *Brit. Med. Journ.* Dec. 3, 1881, p. 806.

by means of one end of the silk, which may have been left to hang through the mouth. After the removal of the plugs, the cavity of the nose should be gently washed out.

CORYZA.

The term coryza designates a symptom rather than a disease. It implies an excessive discharge of altered mucus from the nose. The discharge may be watery and clear, or glairy and thick, or even muco-purulent. It may depend upon catarrhal, strumous, syphilitic, or other affections of the mucous membrane; upon the inhalation of irritants, such as ordinary dust, the pollen of plants, or the other common atmospheric impurities; or upon the presence of a new growth, such as a polypus. If the discharge is free from fœtor, the term 'coryza' is used for this symptom, but if it be accompanied by an offensive odour, the name 'ozæna' is given to it.

The most common cause of *acute coryza* is catarrhal inflammation of the pituitary mucous membrane, or, to use the popular designation, 'a cold in the head.'

This is usually due to sudden atmospheric changes, and especially to exposure to cold or wet, but may also arise from contagion from a person so suffering. It is accompanied by a variable amount of febrile disturbance, and by a sense of fulness and weight about the brow. The nasal membrane is at first dry, and sneezing is frequent; swelling and redness soon supervene, together with increased secretion, which is at first watery, then thick and tenacious, and finally often muco-purulent in character. The discharge is often somewhat acrid and irritates the lip, and there may be at the same time an attack of labial herpes.

After a variable time the symptoms usually subside without any treatment, and the malady is not thought by most persons to be worthy of any special attention. It must be remembered, however, that nasal catarrh is one of the early symptoms of some of the specific fevers, such as measles and diphtheria; and also that an extreme liability to this affection on very slight provocation is often one of the manifestations of a scrofulous or otherwise delicate constitution.

In its earliest stage a 'cold' may sometimes be cut short by a thorough sweating, as by a Turkish bath. Some persons also find benefit from a dose of opium, and from frequent and small doses of quinine. If the secretion is extreme, or painfully irritating, the nose may be washed out with a solution of chlorate of potash (5 gr. to 3j.)

Persons with a very sensitive nasal membrane may with advantage paint the interior of the nose with glycerine before exposing themselves to a cold or impure air.

The *chronic form of coryza* depends either upon the presence of a foreign body or a new growth, or upon certain constitutional conditions.

The first two causes are considered in other parts of this article; it remains to point out the constitutional diseases giving rise to this symptom.

In the infant, inherited syphilis is the most common cause of chronic coryza. It is one of the earliest, and may be for a time the only symptom of the disease, though it is usually succeeded by other manifestations, such as the characteristic eruptions, which aid the diagnosis. The obstruction to the nostrils and the resulting difficulty of breathing and sucking, are often serious embarrassments to the child; and are so marked a feature of the disease as to have given to it the popular name of 'the snuffles.'

In older children the affection is more frequently associated with the scrofulous diathesis, of which chronic inflammation of the skin and mucous membrane is so prominent a symptom. Children thus affected are at the same time subject to ophthalmia, to eczematous eruptions upon the skin, and to enlargement of the lymphatic glands. In many, however, the nasal catarrh is the chief or most obvious symptom, and, like other scrofulous inflammations, is apt to be of great pertinacity. It is in these cases especially that the pituitary membrane, especially that part which covers the inferior turbinated bones, undergoes chronic thickening, a condition which gives rise to troublesome obstruction of the nostrils. This obstruction, and the appearance of the hypertrophied membrane projecting unduly across the nostril,

have led sometimes to the disease being mistaken for polypus; from which it is to be distinguished by its comparative immobility, so that it cannot be brought lower down by blowing the nose; by the absence of pedicle; by its red and velvety surface; and by the fact that obstruction is seldom so complete as in cases of polypus. It is necessary, however, to bear in mind that this condition may be, and often is, associated with the growth of polypi, which it may partially conceal from view.

In adults, chronic coryza depends generally either upon syphilis, or upon an eczematous state of the nasal membrane, chiefly of gouty origin. But in some cases no constitutional tendency can be discovered to account for it.

Syphilitic coryza is commonly met with among the later and more persistent secondary symptoms; but it is very apt to recur from time to time in cases not thoroughly treated, so that it is frequently seen in persons apparently otherwise healthy, long after the original infection. The discharge is variable both in quantity and quality, but is always thicker than natural, usually slightly purulent, and occasionally streaked with blood. On examination the membrane presents thickened and vascular patches, and superficial erosions often coated with an albuminous looking white film. In the syphilitic affection the changes in the membrane are less general and uniform, and more in scattered patches, than in the other forms of chronic coryza, and the diagnosis may be assisted by the history, or other evidences of past or present disease. The discharge which occurs in connection with the tertiary affections of the bones of the nose is almost always offensive, and would therefore bring such cases into the class of ozæna.

In persons of gouty constitution, and especially in those who suffer from eczema, a troublesome coryza is met with, which depends upon an eczematous eruption upon the nasal lining membrane. In these cases there is a general increase of vascularity, and some slight swelling of the membrane, and a good deal of thin watery discharge. The affection is not uncommonly confined to one nostril.

Treatment.—In the treatment of chronic coryza it is of great importance to discover, if possible, the constitutional condition upon which the malady depends.

Infants suffering from inherited syphilis, and in whom the coryza is severe, will require constant local treatment, in addition to the administration of mercury. The nostrils must be kept clear by gentle syringing with weak solutions of permanganate or chlorate of potash, and an ointment of oxide of zinc diluted with oil may be applied by a brush to the nostril and upper lip with great advantage. These cases soon repay attention, for it is remarkable how rapidly these miserable infants improve when properly treated with mercury, aided by such local measures as enable them to suck more easily.

For scrofulous coryza similar local treatment, combined with sunlight, fresh air, and the administration of cod-liver oil, will be found desirable. Chlorate of potash and small doses of iodide of potassium, given in steel wine, are remedies of great value; and a very useful local application is an ointment of ten grains of the red oxide of mercury to half an ounce of olive oil and the same quantity of lard, which must be deposited in the nostril by a soft brush, the ala being squeezed against the septum as the brush is withdrawn. Solutions of borax or tannin in glycerine may be used in the same manner, and if the child is old enough, he must be taught to use the nasal douche.

For the syphilitic coryza of adults the constitutional treatment is of the first importance. Mercury in some form is almost always necessary; the biniodide has seemed to me an especially useful preparation. Local treatment is not of much use, unless the discharge is sufficient to require the nasal douche.

The coryza occurring in gouty persons will be found to be greatly influenced by diet, so that abstinence from those foods which are provocative of gout should be enjoined, and attention should be paid to the state of the digestion. The administration of arsenic in combination with alkalis will almost always be found beneficial; and much improvement is often obtained from judicious purgation. The glycerine of starch is a useful local application.

Cases are occasionally met with in which, with more or less swelling of the naso-

pharyngeal and naso-palatine mucous membrane, there is a peculiar enlargement of the glandular structures belonging to it.

According to Dr. Andrew Clark¹ the racemose and compound follicular glands are especially affected. These glands are most numerous about the posterior nares, round the opening of the Eustachian tubes, and in the roof of the pharynx. Under the influence of this chronic irritation an excessive quantity of viscid mucus is secreted. At a later period pus-like fluid may be discharged. Still later the mucus or purulent secretion, if retained for some time, may become converted 'into little fetid cheesy masses, which are from time to time extruded through the nose or mouth.' Accompanying these conditions the mucous membrane generally is more or less irregularly swollen. The ordinary symptoms are, 'discomfort, aching, or pain in the neighbourhood of the soft palate and posterior nares; tingling or sense of fullness about the root of the nose; frontal headache: a thick mucous, purulent, or cheesy secretion discharged at intervals, chiefly through the mouth, by means of snorting nasal inspirations, followed by hawking; slight perversions of taste and smell; alterations of voice; sometimes temporary deafness from obstruction of one or both Eustachian tubes, and an abundant secretion of wax in the external ear.'²

The treatment is tedious and often unsatisfactory. Mild astringents are to be used with the nasal douche, and attention should be directed to the general health, especially to the condition of the digestive organs, which are frequently disordered in these cases. Purgatives, followed by tonics, are generally indicated, and sometimes cod-liver oil and steel.

In another group of cases, especially described by Dr. Wilhelm Meyer of Copenhagen,³ exuberant growths or vegetations are met with in certain parts of the naso-pharyngeal cavity. These vegetations, when examined microscopically, are found to consist of the so-called 'adenoid tissue,' and are accordingly to be regarded as overgrowths or morbid growths of the closed glandular structures found in or beneath the mucous membrane of the pharynx, the fauces, and the base of the tongue. They vary in form and consistency: sometimes they are solid and firm, and at others soft and highly vascular, and prone to bleed.

The presence of these vegetations in any considerable quantity impedes respiration through the nose, and gives a peculiar 'nasal' character to the voice. There is often some degree of deafness. 'The nostrils are flattened so that the nose appears compressed.' There is deficient secretion from the nostrils, and sometimes blood accumulates in the mouth. Digital examination and rhinoscopic inspection demonstrate the presence of the outgrowths. They are most frequently met with in underfed young people. The treatment consists in removing the vegetations by the knife, or by the galvanic cauter, or by repeated applications of nitrate of silver. Dr. Meyer recommends the use of 'a ring-shaped knife, mounted on a long slender handle, which is passed through one or other nostril, and manœuvred so as to sweep over the mucous surface affected. The bleeding is free but not excessive.' Two or more operations are sometimes necessary. According to Dr. Meyer, the results of this proceeding, supplemented by the use of the nasal douche, have proved very satisfactory.

A copious discharge of watery fluid from the nose has been known to occur in connection with the polypi of the antrum. Sir James Paget has related 'the case of a lady 49 years old, from whose left nostril watery fluid was constantly dropping for eighteen months. 'She was a healthy-looking person, in whom no signs of ill-health or any appearance of disease in or near the nostril could be found. 'There was nothing like polypus, or unhealthy membrane or swelling as of a cyst; no nasal obstruction or unusual flow of tears; no swelling or tenderness; nothing whatever to indicate the source of the fluid.' Six months before the fluid began to flow, the patient had had a blow on the left frontal sinus; besides which she had undergone a great deal of mental distress.

¹ Dr. Andrew Clark, 'On Naso-palatine Gland Disease,' *London Hospital Reports*, vol. i. p. 211.

² Dr. A. Clark, *op. cit.*

³ *Proceedings of the Royal Med.-Chir. Soc.*, October 18, 1889. 'On Adenoid Vegetations in the Naso-pharyngeal Cavity,' by Wilhelm Meyer, M.D., of Copenhagen, Communicated by John Marshall, F.R.S.

⁴ *Clinical Soc. Trans.* vol. xii. p. 43.

It flowed in nearly uniform quantity, a drop running down on the lip every five or six seconds, but was increased by mental distress or physical exertion. None ever came from the right nostril, 'unless when the left nostril and upper part of the pharynx had become filled with fluid during sleep at night; and then, on turning the head downwards and to the right, the fluid poured through both nostrils.'

The fluid looked like pure water; its specific gravity was 1004, it was slightly alkaline, and in 100 parts of the liquid there was 1.15 of solid matter in solution, chiefly chloride of sodium.

Sir James Paget refers to a case of Sir Benjamin Brodie's, in which a lady was twice subject to the dropping of a similar fluid from one nostril. 'First, when she was 26, it began almost suddenly, and so ended after thirteen months. Then, when she was 40, it began slowly, and so ended after twenty-three months. The quantity of fluid discharged was greater than in the case above related; it seems to have been usually two quarts, and once was three quarts in the day.' There was no indication of its source. After the use of sulphate of zinc, locally and internally, the flow ceased. Sir J. Paget advised the same treatment. The patient took a grain of sulphate of zinc, afterwards increased to two grains, three times a day; and injected into the nostril three times a day a solution of sulphate of zinc, three grains to the ounce of water. 'This plan was steadily followed for about six weeks: then the dropping of the fluid gradually diminished, and in two or three weeks more completely ceased.'

A month subsequently, after exposure to mental distress, fatigue and cold, she was attacked with meningitis and died. In the left antrum were found polypoid growths of very fine filamentous tissue infiltrated with serum, and there were signs of chronic catarrh of the lining membrane of the cavity. All the other nasal cavities and sinuses were healthy.

Mr. Dalby has kindly given me the particulars of another case in which this curious symptom was met with. A lady, aged about 30, had a profuse discharge of watery fluid from the left nostril. This occurred first in 1878, when it lasted night and day continuously for ten days, and then suddenly ceased. In 1881 it recurred without apparent cause, and after it had lasted seven weeks she consulted Mr. Dalby. On arriving at his house, the dropping of the fluid suddenly stopped, but after the patient had been engaged in conversation for a short time, and her attention had thus been diverted, the fluid again began to run from the nostril. Mr. Dalby could find no disease of the nose or adjacent sinuses. After lasting three months the dropping of the fluid ceased, not apparently from any treatment, though some weak alkaline injections had been used.

OZÆNA.

Among the diseases affecting the nasal cavities, there is none more troublesome, both to the sufferer and to the surgeon, than ozæna. The essential characteristics of this disease are an offensive discharge from the nostrils, and a peculiar and disgusting fetor of the breath. The latter is sufficient to contaminate the air of the room which the patient occupies, and to debar him from society, and sometimes even from employment; moreover the patient himself is constantly conscious of a most offensive odour. For these reasons the disease is peculiarly distressing, and often affects the health and happiness of the sufferer to an extent quite out of proportion to its inherent gravity. The treatment of the affection requires much patience and perseverance, and its success will depend, as in other diseases, very much upon the correct ascertainment of the cause of the malady.

Ozæna arises from various causes, and is associated with many different conditions; most of the cases, however, may be placed in one of the following three groups: 1. scrofulous ozæna; 2. syphilitic ozæna; 3. traumatic ozæna. But it must be admitted that cases are sometimes met with, which cannot be distinctly referred to either of the causes indicated by the names given above, and of which the origin is not easily discoverable. These, for the want of a better name, may be called cases of 'idiopathic ozæna.'

First of all, it will be convenient to describe the symptoms common to all the

varieties of *ozæna*. They are chiefly these: (a) A constant discharge of diseased secretion from one or both nostrils. This discharge is usually a thin muco-purulent fluid, mixed with epithelium, and occasionally streaked with blood. Sometimes it consists chiefly of a gelatinous material, with little or no pus in it; or it may resemble thin gruel. Much of this discharge finds its way through the posterior nares into the pharynx; it also, of course, escapes by the anterior nares. The discharge, of whatever kind, is very offensive, and the breath has an indescribable and most disgusting fœtor. (b) The sense of smell is either abolished or materially interfered with, and the patient is conscious of a fœtid odour. (c) There is usually some tenderness of the nasal walls, and often frontal headache.

The most common cause of *ozæna* is *scrofula*; and as *scrofula* is a disease of childhood, we find, as might be expected, a large number of the cases of *ozæna* occurring in children and young persons. It must not, however, be supposed that all the cases of *ozæna* seen in children are of a scrofulous nature, though the majority of them are so. A considerable number of them have their origin in syphilis.

The scrofulous cases usually show other signs of the diathesis, but in addition to the symptoms described in connection with scrofulous coryza, an examination of the nose often reveals a number of small pustules and ulcers dotted over the surface of the swollen mucous membrane. Upon these ulcers crusts form, which, with the swollen membrane, tend to block up the nostrils, and to retain the secretion in the sinuses. It is probably to the retention and decomposition of this secretion that the fœtor in many cases of *ozæna* is due; it can therefore be to a great extent overcome by the frequent cleansing of the nasal cavities by antiseptic solutions. But there are other cases, those in which the fœtor is most horrible, in which such treatment does no more than somewhat lessen the odour, and has no curative effect upon the disease. Such cases I believe to be due to the presence of dead bone, and to be curable only by its removal.

In many of the cases of scrofulous *ozæna* there is not only ulceration of the mucous membrane, but also necrosis of the bones of the nose—a fact which is not surprising when we remember how often, in other parts of the body, *scrofula* gives rise to bone-disease.

Next to *scrofula*, *syphilis* is the disease which most commonly gives rise to *ozæna*. The affection commences either as a tertiary ulceration, or as a gummatous periostitis. The ulceration often occurs chiefly at the back of the nostrils, and is seen best by posterior rhinoscopy. The ulcers are in some cases quite superficial, and coated with the peculiar albuminoid film often seen on those of the throat and tongue. In others the ulcers are deep, and have excavated edges, and are covered with sloughs. In all, the ulcers are irregular in shape, often running one into the other, and having a tendency to spread in one direction while healing in another. There is less swelling of the mucous membrane than in scrofulous *ozæna*; and the ulcers in syphilis are larger, less numerous, and more irregular in shape. After a time the bones become diseased; and these are amongst the most offensive cases of *ozæna*. Or the bone disease may be secondary to gummatous periostitis, which often leads to extensive necrosis. The affection occurs both in acquired and in inherited syphilis, and is usually accompanied with other syphilitic symptoms.

Traumatic ozæna may arise either from a blow upon the nose, giving rise to periostitis and subsequent necrosis of the bone, or may be the result of the introduction of a foreign body into the nostril.

As might be expected, the cases arising from a blow usually (probably always) are connected with the presence of necrosed bone. They are therefore favourable for operative treatment, and may be subjected to it at an earlier period than the other varieties of *ozæna*. There is but slight swelling of the mucous membrane, and no ulceration except at the situation of the dead bone, which is often beyond the area of sight or touch.

Ozæna arising from the presence of a foreign body is seen sometimes in children, who have been known to thrust a variety of substances into the nostrils—such as peas, beans, beads, pieces of pencil, wool, &c. It is well to bear in mind the possibility

of such a cause for cases of *ozæna* occurring in children with no evidences of constitutional disease. A foreign body may give rise either to ulceration of the mucous membrane alone, with offensive discharge, or there may be caries of the bone also. If there is no bone-disease, the removal of the offending substance soon produces a cure, as the fœtor of the discharge is in great part caused by its being pent up in the nose, from the difficulty of exit produced by the presence of the foreign body and the accompanying swelling.

Besides these there are cases of *ozæna* which cannot be placed in either of the above-named groups, and which it is convenient to class together under the name of *idiopathic ozæna*. They are seen sometimes in perfectly healthy people, in whom no cause can be discovered: but a good many occur in children who have recently had one of the acute specific diseases, *e.g.* scarlatina or measles; and I have seen several in young women with disordered menstruation. This form of the disease appears to me to be much more common in women than in men. In such cases there is usually only slight swelling of the nasal mucous membrane, which, however, is of a bright red colour, with here and there velvety raised patches, which easily bleed. There are often no visible ulcers, and I think in the less offensive examples, no disease of the bone. Yet doubtless in some the bones become affected, and it is upon the presence or absence of bone-disease that the possibility of curing the patient without operation depends.

It ought to be mentioned that in some cases of *ozæna* the frontal sinuses are involved in the disease, and large quantities of purulent fluid collect in these cavities, giving rise to intense pain and distress. A prominent symptom in these persons is sleeplessness, as has been pointed out by Mr. Cesar Hawkins. I have seen very great distress caused by this sleeplessness, and the frequent nightmare which occurs when sleep is obtained. The pain and sleeplessness gradually increase as the sinuses become more distended, and there is often some œdema of the upper eyelid and brow. A copious discharge then takes place through the nostrils, and the patient is for a time relieved. Of course if the discharge does not occur, the sinus may become so much distended as to cause displacement of the eyeball; or the matter may make its way externally or even into the cranium. Usually, however, there is a periodical collection and discharge of the secretion, in the manner I have described.

The treatment of *ozæna* must of course depend in each case upon the cause of the disease, and the particular variety with which we have to deal; and I need hardly say that our first step should be a thorough examination, both of the constitutional condition of the patient, and of the part concerned in the disease.

It will be well to have the nose thoroughly cleansed by the nasal douche before making the rhinoscopic examination. The method of washing out the cavities of the nose is a practical application of a physiological fact discovered by Professor Weber of Halle; viz., that when one side of the nasal cavity is entirely filled through one nostril with fluid by hydrostatic pressure, while the patient is breathing through the mouth, the soft palate completely closes the choanæ, and does not permit any fluid to pass into the pharynx, while the fluid easily passes into the other cavity, mostly round and over the posterior edge of the septum narium, and escapes from the other open nostril, after having touched every part of the first half of the cavity of the nose, and a great part—certainly the lower and median canals—of the second half.¹

The apparatus required consists of a yard of elastic tubing to one end of which is attached a perforated india-rubber nozzle to fit the nostril; to the other end of the tube is fitted an india-rubber bag or glass vessel for holding the fluid to be used: or it may be connected with a piece of metal tube bent as a syphon, or terminated by a small metal funnel which is sunk in a jug containing the liquid.

The method of using the nasal douche is illustrated by fig. 144. The receptacle is filled with the liquid to be used, and placed on a level somewhat above that of the head of the patient. The precise height may be varied according to the degree of force with which it is desired that the stream should flow.

The tube is either filled by the simple descent of the fluid, or, if the syphon action

¹ Thudichum, *On Polypus in the Nose and Ozæna*, p. 17. (Churchill, 1869.)

is adopted, by pouring a sufficient quantity of fluid into it, and then immersing the footpiece in the jug, &c., or by drawing fluid into the tube after the footpiece has been immersed.

The nozzle is then held in the nostril, the patient being seated with his head slightly inclined over a basin, and breathing only through his mouth. In this way a gentle stream of fluid is passed in at one nostril, round the posterior border of the septum, and out at the other nostril. The force of the stream will be in proportion to the height at which the receptacle is placed, and should not be greater than is just sufficient to carry the liquid through.

FIG. 144.—Method of using the Nasal Douche.

This is the most efficient plan, not only of cleansing the nasal cavities, but also of applying medicated solutions to them. It is desirable to use some fluid of higher specific gravity than water; and for simply washing out the nose a solution of common salt, a teaspoonful to a pint of water, answers very well.

In the treatment of *scrofulous ozæna*, the constitutional remedies will be more important than the local. The patient should, if possible, reside at the seaside, and be placed under the most favourable hygienic conditions; and cod-liver oil and iodide of iron¹ should be given regularly for long periods. The digestive organs should be carefully attended to, and the food properly selected. The local treatment chiefly consists of the frequent washing out of the nasal cavities with saline solutions, such as that of common salt or of phosphate or carbonate of soda. Another solution that I have found useful is one of chlorate of potash and tincture of myrrh, two drachms of each to a pint of water; or permanganate of potash may be used, in the proportion of two drachms of Condyl's fluid to a pint of water. But whatever may be selected, frequent changes will be found beneficial. If after a long perseverance with this treatment there is no improvement, the nasal cavities should be carefully explored during anæsthesia, as in all probability diseased bone will be found. Dr. Rouge of Lausanne, in a most interesting paper upon the subject,² has published eight cases of long-standing *ozæna*, in all of which he has found and removed dead bone from the cavities of the nose. Dr. Rouge has moreover invented an ingenious operation for the purpose of obtaining free access to the nasal cavities, which enables the surgeon to discover and remove with ease any dead bone therefrom.

The operation consists of separating the soft parts of the nose from their bony framework, by incisions through the mucous membrane where it is reflected from the upper lip on to the gums. The lip and nasal cartilages are then lifted completely up towards the forehead, when the nasal sinuses can be explored with the greatest facility. The parts being replaced, no deformity whatever results, nor is there any visible scar. The operation is, I think, a very valuable one, and will be found applicable to other conditions besides that for which Dr. Rouge has used it. I shall subsequently refer to an instance in which I removed polypi by this method. Of Dr. Rouge's eight patients, all were cured except one, in whom, after a second operation in which a considerable portion of the ethmoid bone was removed, death occurred from meningitis.

¹ The best mode of giving this medicine is, I think, by dissolving iodide of potassium in steel-wine. I believe the syrup of the iodide of iron to be an almost useless preparation.

² *Nouvelle Méthode pour le Traitement chirurgical de l'Ozène*, par le Dr. Rouge, Chirurgien de l'Hôpital Cantonal, à Lausanne, 1873.

I have myself treated four intractable cases of *ozæna* by this operation, and in each case have discovered necrosed bone. In two cases the operation was completely successful; the dead bone being removed, the discharge ceased without further trouble. But in one case, though the patient was temporarily cured, after eighteen months the discharge recurred, and I presume there was fresh necrosis; and in a fourth instance, though I was able to remove two pieces of necrosed bone, there remained a large exposed surface at the base of the skull. I saw this patient about a year after the operation, when the nostril was still discharging; there was no perceptible *ozæna*, but the nasal douche was used daily so as to keep the cavities thoroughly clean.

While fully appreciating the ingenuity and value of the operation, I confess that I am not inclined to expect quite such favourable results as Dr. Rouge so fortunately obtained, chiefly because there are a considerable number of cases of *ozæna* in which there is a carious surface at the base of the skull which cannot be removed, and as long as this remains unhealed the discharge will continue.

Moreover I have found by experience that more free access than would be supposed can be obtained to the nasal cavities by placing the patient under an anæsthetic and pushing the septum on one side, and by this means I have in several cases been able to discover and remove dead bone, the presence of which I could not otherwise ascertain. The nostril having been explored, the displaced septum can be pushed back into its place, and as far as I have seen, no harm results.

Still there will always remain some cases in which no such measure avails, and for these we have a valuable resource in Rouge's operation.

Syphilitic ozæna requires the constitutional treatment of the disease of which it is a manifestation. Mercury must be given, and its influence gently maintained for a considerable period. This is best done by the calomel vapour-bath, or by inunction. If for any reason, however, the medicine cannot be given by the skin, I think the gray powder or the perchloride are the best preparations. Iodide of potassium and freshly-made decoction of sarsaparilla are also useful in combination with the mercurial treatment, and such tonics or other medicines as the general state of the patient may indicate. Infants and young children—the subjects of inherited syphilis—bear mercury given internally better than adults; and for these, either the mercurial belt or the gray powder should be used. Cod-liver oil may often be advantageously given at the same time.

Locally, I think, when the bone is not affected, the best application is an ointment composed of fifteen or twenty grains of the red oxide of mercury with half an ounce of olive-oil and half an ounce of lard. This should be applied with a brush after the nose has been washed with the nasal douche. The ammonio-chloride of mercury ointment, diluted with oil, is also useful. In syphilitic patients operative interference should be deferred until the constitutional treatment has been thoroughly carried out, so that there may be a probability of the bone-disease having come to an end, and a cure resulting from the removal of any sequestrum that may be found.

Ozæna, the result of the presence of a foreign body in the nose, usually requires for its cure only the removal of the offending substance, and the frequent washing out of the nasal cavities by some antiseptic solution, such as that of permanganate of potash or common salt. When there is a distinct history of a blow, operative treatment may be hopefully undertaken after a few months' trial of milder measures; for the discharge probably depends upon the presence of necrosed bone.

For cases of *idiopathic ozæna*, the treatment must be chiefly local; yet it is important to carefully search for, and treat, any disturbance of the health that may exist. The local treatment that has seemed to me most useful consists of the frequent use of a lotion of chlorate of potash and tincture of myrrh. It is well, however, to vary the application, and for this purpose the glycerine of tannic acid, dilute mercurial ointments, creosote ointment ʒj. to ʒj. of cerate, solutions of carbonate of soda and of quinine, may be found useful.

In the treatment of this form of *ozæna*, Trousseau speaks most favourably of the insufflation of various powders. Among those most generally applicable are the sub-nitrate of bismuth combined with an equal proportion of talc; chlorate of potash by

itself, or with seven or eight parts of sugar; borax, similarly diluted; the ammonio-chloride of mercury powder, eight grains to an ounce of sugar; calomel, with twenty to thirty parts of talc, &c. The effects of the insufflation of the mercurial powders should be very carefully watched, and the insufflation should not be too frequently repeated. Two or three times a day is generally often enough. But the other powders may be used much more frequently, almost *ad libitum*. In all cases it is important to wash out the nose thoroughly before blowing in the powders. It not unfrequently happens that the thorough cleansing of the cavities and subsequent insufflation of the powder is followed by the abolition of the foul odour, for the odour belongs to the discharge, but when the discharge collects again the odour returns.

The best instrument for blowing the powders into the nose is Rauchfuss's Insufflator (fig. 145). The powder is introduced into the tube through the opening (a), which is then covered over by the sliding tube (b), the extremity (c) is introduced into the nasal cavity, and then by a sudden compression of the india-rubber ball (d) the powder is driven out, and diffused in all directions.

FIG. 145.—Rauchfuss's Instrument for blowing Powders into the Nose.

Many of these cases require great perseverance, and some of them have seemed to be benefited by nothing. For such as resist the treatment indicated above, we have the resource of Rougé's operation.

BLOOD-TUMOURS AND ABSCESS OF THE SEPTUM.

Blood-tumours of the septum are always the result of injury. They are often accompanied by fracture, and usually affect both sides of the bone.

The mucous membrane is raised by the effusion, and forms a swelling which may even be sufficient to impede respiration.

Treatment.—If any treatment is thought necessary, the local application of cold may be resorted to.

Abscess of the septum may be acute or chronic. The acute form is usually caused by injury. The integument of the nose becomes œdematous and tender on pressure; the pituitary membrane is inflamed, and the portion covering the septum is uniformly turgid; the secretion of mucus is diminished; and there is more or less febrile disturbance. At a later period matter is formed beneath the mucous membrane; and a prominent swelling, causing proportionate obstruction, appears in one nostril or both. The inflammation may spread to the frontal sinuses and lachrymal passages; and headache and epiphora may result. Sometimes the lower margin of the septum and the upper lip become affected. The swelling itself is red, shining, tender, and fluctuating on pressure.

Treatment.—As soon as matter has formed it should be evacuated by incision, in making which, the thickened state of the mucous membrane must be borne in mind. The opening must be kept patent as long as any pus is secreted, and the inflammation allayed by warm fomentations.

Chronic abscess of the septum sometimes commences without any assignable cause and progresses very insidiously. The inflammatory stage is sometimes so slight as to pass unheeded; and the patient is not aware that anything is the matter till the abscess is fully formed; and then suffers not so much from actual pain as from uneasiness felt in the nares. In these cases the outer surface of the nose is never involved. In this form of abscess there is less redness, tension, and tenderness on pressure than

in the acute form. The abscess, besides, is more extensive, and more likely to occur singly on either side of the septum. It may communicate with a collection of fluid situate outside the nose—in the upper lip, for example. The matter secreted has sometimes a highly offensive smell.

The swellings formed by such abscesses may possibly be mistaken for polypi, unless care is taken in the diagnosis. They are still more likely perhaps to be confounded with the thickened elongated condition sometimes presented by the mucous membrane of the septum.

These abscesses should be opened early; and care must be taken to prevent the re-accumulation of matter, by passing a probe into the opening daily; or the cavity may be syringed with a weak detergent solution.

A guarded prognosis should always be given in these, as in other affections of the septum; for there is always danger of the destruction of parts of the bones or cartilages, which sometimes results in the formation of a permanent opening through the septum.

If such an opening through the septum be small, a very disagreeable whistling is sometimes produced when the patient speaks. In such cases the opening may be enlarged with benefit.

NEW GROWTHS.

Various forms of new growth are met with in the nasal cavities. They may be classified as follows:—

1. Papillary growths.
2. Polypi.
 - (a) gelatinous.
 - (b) fibrous.
 - (c) malignant.
3. Cartilaginous and osseous growths.

PAPILLARY GROWTHS.

Cases occasionally, though rarely, occur in which the nostrils are obstructed by papillary growths springing from the mucous membrane. Such growths bear a general resemblance to the papillomata of the mucous membranes of other parts, and are sometimes associated with similar growths upon the palate. They are usually, if not invariably, met with in children or young people. They give rise to a variable amount of irritation, and if extensive, obstruct the respiration and alter the voice.

They should be removed by scissors, and the base touched with solution of iron.

MUCOUS, GELATINOUS, OR VESICULAR POLYPI.

These are by far the most common of all the abnormal growths met with in the nasal cavities. They may be regarded as localised hypertrophies or outgrowths of the mucous membrane and submucous tissue. They are soft and somewhat elastic in consistence; of yellow or grey colour, and shining and semi-transparent appearance. They are, as a rule, pedunculated and pendulous, and may be more or less easily moved by the finger or a probe. Sometimes they are moved to and fro during respiration, and may be brought to a lower level by forcible expiratory efforts. They occur singly or in numbers. Sometimes they are irregularly lobulated, and fit themselves to the cavities in which they lie. When incised and submitted to pressure a variable quantity of fluid exudes. Superficially, they are often seen to be traversed by a few fine blood-vessels.

Microscopical examination shows that these polypi are related to the 'myxomatous' tumours of Virchow. They consist of extensions of the mucous membrane, including more or less closely reticulated fibro-cellular structure, which is continuous with the normal submucous tissue. Their surface is covered by ciliated epithelium;

and their substance is made up of delicate, wavy, interlacing filaments, the interstices of which are occupied by fluid, or semi-fluid material, containing round, oval, elongated, or caudate cells with nuclei, and very fine granules or molecules. The normal mucous glands, according to Billroth,¹ are enlarged and converted into lobulated growths with very numerous sacculi, and these help to make-up the mass. In some cases these sacculi become cystic in appearance, and the 'vesicular' character of the polypi is pronounced. In other cases the connective-tissue elements are developed in larger proportion, and the growths are consequently firmer and denser and approach in character the fibrous polypi. Occasionally the softer polypi become comparatively condensed and opaque in places; and in some rare instances concretions of fibro-cartilaginous hardness are found in them.²

These polypi are most frequently connected with those portions of the mucous membrane which cover the superior and middle turbinated bones and line the superior and middle meatuses. Sometimes they arise in the lower meatus, or are attached to the inferior turbinated bone; sometimes they spring from the roof of the nose; occasionally they grow from the ethmoidal cells, or even from the frontal sinuses into the nasal cavities. But they very rarely, if ever, spring from the mucous membrane covering the septum.

In cases in which there are several distinct polypi, the lowest or most anterior, having the open nostril before them, make their way downwards uncompressed; but the others are kept up and hidden from sight, and become more or less compressed and hindered in their growth. For this reason, if the lowest only is removed, those above descend and rapidly increase in size. Sometimes they grow chiefly backwards, and may then hang down into the pharynx.

It is very rare to see any material alteration of the shape of the nose produced by the growth of this form of polypus.

The earliest symptoms of *mucous polypus* in the nose are a sense of fulness and weight in and about the nostril affected; frequent sneezing; and more or less mucous discharge. For a long time before the growth becomes visible, the patient seems to be always 'catching cold.' As the growth increases other symptoms supervene; respiration through the nose becomes more embarrassed; the patient cannot blow through the affected nostril, or the air passes with a whistling noise; he is obliged to keep his mouth constantly open; during sleep he lies with his head thrown back, and often snores; the voice is more or less affected, and becomes thick, indistinct, and 'nasal' in character; the sense of smell is impaired, or altogether abolished; the sense of taste is affected in so far as it is dependent upon a perfect condition of the olfactory organs; deafness sometimes occurs, either from obstruction to the Eustachian tubes, or from coexistent thickening of the lining membrane of the tympanum; there is increased mucous discharge, which is rarely offensive. Occasionally, but not often, there is epistaxis, in this respect contrasting with fibrous polypi and malignant growths. Sometimes the lower orifice of the nasal duct becomes obstructed, and there is overflow of tears. These various symptoms become aggravated in damp, and somewhat alleviated in dry weather; for the polypi are 'hygrometric' in character, and are notably affected by the state of the atmosphere. In dry, warm weather they contract; and in moist or wet weather they enlarge, and become fuller, and paler in colour. Sudden atmospheric changes are liable to give rise to severe fits of sneezing.

The diagnosis may usually be made secure by rhinoscopic examination, though in the early stages of the disease it is not always possible to obtain a view of the growths or to reach them with the finger.

In doubtful cases much assistance may be obtained from the administration of an anæsthetic, and the careful exploration of the nostril with the finger.

It is well to remember that hypertrophy of the mucous membrane covering the

¹ See Weber, in 'Pitha und Billroth,' *op. cit.* p. 203. Billroth, *Ueber den Bau der Schleimpolypen*. Berlin, 1856.

² See case referred to by Gross, *op. cit.* vol. ii. p. 338.

inferior turbinate bone may produce some of the symptoms of polypus, from which it is to be distinguished by its immobility and difference in colour.

The most important point in the diagnosis is to distinguish the benign mucous polypus from other growths of more serious nature. The light colour, semi-translucency, and soft elasticity of the mucous polypus; its slow progress, the absence of frequent hemorrhages, and the general good health of the patient, serve to distinguish this growth from the fibrous polypus, which is more or less red in colour, opaque, and resistant, and which usually increases rapidly, undergoes no change of volume with change of weather, and is usually accompanied by frequent epistaxis. Malignant growths may be distinguished by their colour, opacity, consistence, and fixity, as well as by their proneness to bleed when touched, and by the comparative foulness of the discharge to which they give rise.

Osseous and cartilaginous growths are distinguished by their hardness, fixity, origin, and mode of growth.

Mucous polypi are always very troublesome, but rarely lead to serious results. Now and then they subside, and a spontaneous cure is effected. But it is never worth while to await such a result; for the growths may almost always be removed without much pain, and with scarcely any risk. They are, however, very liable to grow again, especially if any portions are left unremoved, or the patient is unwilling to persevere in the necessary course of treatment.

Treatment.—The only treatment that can be recommended is the removal of the growths by operation as completely as possible.

Attempts have been made from time to time to obviate the necessity for operative measures by the use of various escharotic, astringent, and exsiccative applications. 'Dr. J. H. Reeder of Illinois published the particulars of two cases in which prompt cures were obtained by strong injections of the tincture of perchloride of iron, aided by the application of a piece of sponge moistened with a solution of this article to the cavity of the nose.'¹ Mr. Erichsen refers to a case in which 'after the assiduous use of chloride of zinc injections, a very copious discharge of large sloughy polypoid masses took place from one nostril, which had been blocked up for many months previously.'² Nélaton recommends in some cases the repeated application of solid nitrate of silver;³ and Mr. Bryant has advocated the insufflation of tannic acid in powder.⁴ But as a rule such kind of treatment is only palliative, and is not productive of any permanent benefit.

Various methods have been devised for the removal of nasal polypi by operation. That most commonly adopted consists in the avulsion of the growths by means of forceps. The forceps should be about seven or eight inches in length, and strong, but as slender as may be consistent with strength. The blades should be grooved longitudinally, and well serrated along their edges. They may be curved or straight. In most cases straight, or nearly straight, forceps are best, but if the polypi are situated far back, or hang down into the pharynx, and have to be removed through the mouth, curved forceps are required.

The patient should be seated with his head thrown back and supported by an assistant, in such a posture that the cavity of the nostril is well illuminated. The tip of the nose is elevated by the operator's left thumb, or the nostril is dilated by a speculum.

The point of attachment of the polypus having been ascertained as exactly as possible, the growth should be seized close to its root, and twisted or torn off by steady traction and appropriate movements of the forceps.

It is sometimes convenient to pull gently upon the body of the polypus with one pair of forceps, while the blades of a second pair are slid gently along its neck until the root be reached and grasped.

When all the visible growths have been removed, the nostril should be carefully explored with the finger, as other small ones may often be thus detected and removed.

It is seldom necessary to give an anæsthetic, and if the patient have moderate

¹ Grooms, *op. cit.* vol. ii. p. 340.

² *Science and Art of Surgery*, vol. ii. p. 287.

³ *Pathologie chirurgicale*, tome ii. p. 670.

⁴ *Lancet*, Feb. 1867, p. 285.

resolution it is undesirable to do so, for a good deal of assistance may be obtained from the patient blowing through the nostril, and thus clearing it of blood, and bringing down the growths.

When the polypus is situated far back and hangs down into the pharynx, it may sometimes be seized and removed by means of properly curved forceps introduced through the mouth. But it is generally easier to detach the polypus by means of forceps introduced through the nostril, and then to push it on into the throat.

In some instances polypi may be successfully removed by the fingers alone. One forefinger is thrust into the affected nostril, and the other is introduced into the posterior nares through the mouth. When the growth is reached, and held between the two fingers, it is pushed backwards and forwards until all resistance has ceased, and it is then withdrawn through the nearest opening.

Some surgeons advocate the removal of polypi with a wire snare, such as that invented by Mr. Hilton; and Dr. Thudichum uses for the purpose the galvano-caustic wire, by which the growth is burnt off.

My own belief is that nothing is so convenient or effectual as avulsion by forceps; for if the blades move with perfect smoothness (a very important point), and are held lightly by the fingers, the surgeon can feel his way with them up to the root of the polypus, and thus ensure its complete removal.

The objection sometimes advanced to the use of the forceps, that it is apt to lead to the removal, with the polypus, of a portion of the mucous membrane from whence it grows, does not seem to me to be material. For the loss of a little piece of mucous membrane, or even of a fragment of the turbinated bone, is not of the slightest consequence, whereas the removal of the whole of the polypus is essential for the cure; and in cases in which troublesome recurrence has taken place, it is quite justifiable to remove intentionally the portion of bone to which it is attached.

The hæmorrhage, though sometimes free, usually ceases spontaneously, or may be easily arrested by the injection of cold water or astringent solutions. But, if the polypi be numerous, and there is much bleeding, and especially if the patient has suffered severely, it is better to defer the completion of the operation to a future period. And thus it often becomes advisable to operate on several occasions, and to remove the growths successively, rather than to overtax the endurance of the patient by attempting too much at a single sitting.

After the nostrils have been cleared of polypi, it is often possible to feel with the finger, or to see, upon the mucous membrane, numerous little gelatinous granulations or buds; in other cases the membrane is simply thickened and vascular.

In either instance it is advisable to apply for a time some astringent solution or powder; and in all cases, after the removal of polypi by operation, the nasal douche should be used for a few days.

In some cases the insufflation of tannic acid, or a mixture of one part of the ammonio-chloride of mercury to sixty of powdered sugar, proves of great service, either in hindering the development of fresh growths, or in aiding the destruction of such portions as may have had their vitality impaired by the operation. The little buds left upon the mucous membrane, if not destroyed, will almost certainly develop into fresh polypi, and hence the frequent recurrence of these growths after removal. In such cases I have lately adopted the practice of applying to the interior of the nostril the strong solution of perchloride of iron, and with very satisfactory results. It should not be used till a day or two after the operation, and is best applied by a piece of lint soaked in the solution and attached to forceps or a probe.

In one case I performed Rouge's operation to obtain more complete access to the nose for the removal of polypi.

A man, aged 50, was admitted into St. George's Hospital in Aug. 1875, with both nostrils full of soft polypi. He had had the polypi removed a great number of times, but immediate recurrence had always taken place, and he was anxious to know if something more effectual could not be done. He was an intelligent man, and I explained to him that I thought the growth could be more completely removed by Rouge's operation, to the performance of which he willingly consented. On August 27 I therefore lifted the nose after the manner described, dividing both septum and alæ. This gave a free access to the nostrils, and

I removed the growth easily, and also a number of minute buds from off the walls of the nose. He went home in a fortnight quite well, and at the end of the year there had been no recurrence.

I do not think, however, that this somewhat severe operation¹ can often be necessary for the cure of polypus, and at the time I resorted to it I had not used the perchloride of iron, which I have since found so efficacious in preventing recurrence.

FIBROUS POLYPI.

Fibrous polypi are by no means so commonly met with in the nasal cavities as the softer growths described in the preceding pages, but they are far more formidable. If allowed to take their course, they give rise to the most serious results. Their extirpation is often very difficult, and sometimes impracticable; and, moreover, the operative measures requisite may be attended by considerable risk.

These growths spring from the periosteum, and are connected with it by continuity of structure. They are covered by an extension of the mucous membrane, sometimes comparatively thick, but more frequently thinned away. As a rule, they occur singly, but in some rare instances two or more distinct growths have been found.¹ They vary very much in shape and size, but as a rule they are elongated and of very irregular contour, presenting finger-like prolongations, rounded out-growths, or broad based lobules in those parts which have encountered least resistance. They are firm and resistant to the touch, and are sometimes of almost cartilaginous hardness. They are opaque and usually more or less red in colour—in some cases comparatively pale, in others dark or even purplish red. When removed from the body, they are generally dull white or yellowish. But the tint varies in different specimens, and in different parts of the same specimen. They are traversed, not only superficially, but also throughout their substance, by numerous thin-walled blood-vessels, which are sometimes varicose. Hence their proneness to bleed. They are composed for the most part of closely-woven strands of white fibrous tissue, which spread out from the pedicle. They contain very few elastic fibres. In different specimens a variable proportion of spindle-shaped nucleated cells, similar to those of sarcomatous growths, are to be found.

Instances are on record in which deposits of carbonate and phosphate of lime have taken place on the surface of these growths,² as well as others in which the growths themselves have undergone a process of partial calcification.³

Fibrous polypi occasionally spring from the periosteum of the lateral walls of the nasal cavities or pterygo-palatine fossæ, or from the floor of the nose.

In some instances they appear to have originated in the antrum, and to have extended from thence into the nose. But in many cases, in which they have been supposed to have taken such a course, further investigation has shown their origin to have been very different.⁴

There can be no doubt, however, that polypi of the kind under discussion most frequently take origin from the periosteum of those portions of the base of the skull which form the roof of the naso-pharyngeal cavity. In such case they are called 'naso-pharyngeal polypi.'

The periosteum of the basilar process of the occipital bone, the body of the sphenoid bone, and the immediately adjoining parts, is peculiarly thick and vascular. The blood supply is very free, and derived from several different sources; hence, perhaps, its liability to give origin to new growths, and the rapidity with which such growths often increase in size.

The naso-pharyngeal polypi, properly so-called, invariably spring from some part or other of the limited area thus indicated. They are, however, prone to acquire

¹ MM. Lallemand and Cruveilhier record the case of a young man in whom were found, on post-mortem examination, two polypi of the kind under discussion. One grew from the posterior part of the superior turbinated bone and adjoining parts on the left side, the other from below the opening of the sphenoidal sinus on the right side.—*Dict. en 24 vol.*

² H. Oloquet, *op. cit.* p. 688.

³ Bourdilliat, *Gazette médicale*, 1868; 'Tumeur calcifiée.'

⁴ This was notably the case in the very remarkable instance narrated by Mr. Prescott Hewett, *Med.-Chir. Trans.* vol. xxiv.

secondary attachments, and thus may arise various sources of difficulty in arriving at a satisfactory conclusion as to their point of origin. Sometimes they become adherent to the walls of the nose, and consequently may be supposed to be nasal polypi. Occasionally they extend down behind the pharynx, and in such cases may appear to have arisen from the anterior surface of the spinal column.¹

Whatever their origin, these polypi increase in size with comparative rapidity. At first they mould themselves somewhat to the cavities in which they lie, and grow forwards, or backwards and downwards, in the direction of least resistance. When more advanced, they exert injurious pressure from within upon the walls of the nasal cavities, and in a certain sense overcome the resistance they encounter. They are liable to cause ulceration and destruction of the mucous membrane, perforation of the septum, and expansion and displacement of the nasal bones and superior maxillæ; or gradual thinning and absorption of these bones may result from the pressure to which they are subject. The palate is pressed downwards and forwards; and the cavity of the mouth is encroached upon. In all such cases the visage is proportionately distorted. The cheeks become more or less prominent, and the nose expanded and flattened. The eyes appear, or actually are, more widely apart than natural. The general aspect thus produced is very characteristic. It has been not inappropriately termed 'frog-face.' In some cases the distortion is symmetrical. In others, one side is more obviously distorted than the other. If one side only of the face is affected, the other remaining perfectly natural, the presumption is that the disease, whatever it may be, is in the antrum rather than in the nose, although the cavities of the latter may be encroached upon.

In the earlier stages the *symptoms* are similar to those produced by the mucous polypi, and it may be difficult to make the diagnosis. But the fibrous growths are firmer and more fixed than the mucous, and they do not undergo any change of volume under different atmospheric conditions. The symptoms, therefore, are more severe and more constant, and when the nose is once blocked, the obstruction to respiration is more absolute and unyielding. Moreover the fibrous polypi give rise to frequently recurring epistaxis. This is not only a very characteristic symptom, but it may prove the source of much anxiety and danger. The discharge from the nose associated with the presence of a fibrous polypus is as a rule more scanty, and thinner, more sanious, and more liable to become foul and ozenic than the mucous discharge usually associated with the presence of the softer growths.

In the later stages, when the polypus can be distinctly seen and felt by the surgeon, and still further when from its size it has caused distortion of the face there can be little or no difficulty in making out the nature of the growth, whatever doubt there may remain as to its precise origin and connections. Careful exploration, and pressure in different directions alternately by the fingers, and the passage of a bent probe round the free parts of the polypus, first on one side, then on the other, may often afford reliable indications of the probable position of the original pedicle, as well as of such secondary attachments as may have been formed.

Naso-pharyngeal polypus, if left to pursue its course, soon presses upon the soft palate, and thus interferes with easy deglutition, and gives rise to frequent inclination to vomit. Sometimes, when attempts are made to swallow, liquid portions return through the nose. As the malady advances, thin, sanious, or purulent, and sometimes fetid discharges begin to flow more or less abundantly from the nostrils, and the epistaxis becomes more frequent and more severe. The growth generally enters one side of the nose first, and then invades the other either by penetrating the septum or by growing round its posterior border. Still later, the spongy bones and septum become more or less extensively destroyed, in consequence of the pressure of the growth. The nasal bones and superior maxillæ also become destroyed to a

¹ These several points are ably discussed in the Treatise of Dr. Robin Massé, *Des Polypes naso-pharyngiens*, Paris, 1864; and also in the elaborate essay of M. d'Ornellas, *Des Polypes fibreux de la base du Crâne, dits naso-pharyngiens*: Paris, 1864. And in the essay by M. Beuf on the same subject; Paris, 1867. Also by M. Brevet, *Des Polypes naso-pharyngiens*; Paris, 1856.

variable extent, or expanded and pushed to either side; and the countenance is consequently distorted. Sometimes the growth enters the maxillary sinus, and presses upon the floor of the orbit; sometimes it seems to pass round the bone (or through it), and issues under the skin of the cheek, passing along the cutaneous aspect of the bone, and pressing together the walls of the antrum.¹

Sometimes the growth sends off prolongations through the sphenopalatine and sphenomaxillary openings, and even extends under the zygomatic arch into the temporal fossa. MM. Maisonneuve and Chassaignac record cases in which growths of this kind had penetrated the pterygomaxillary fissure, and passed through the pterygoidean space between the muscles towards the face.² In other cases extensions are sent into the frontal and sphenoidal sinuses. And in others, again, prolongations may pass through the sphenomaxillary fissure into the orbit, with or without destruction of bone, and so cause protrusion of the eyeball.³ As a further consequence, the optic nerve may be put on the stretch, and vision may be impaired. Very frequently the orifices of the Eustachian tubes are obstructed, and the sense of hearing is dulled. Very frequently, also, the nasal ducts are compressed, and more or less constant epiphora results. But the most serious consequences follow when, as occasionally happens, the growth penetrates to the interior of the skull. In such case no treatment is of any avail. The growth may enter the skull either through the sphenoidal fissure, or, after having caused absorption of bone, from the sphenoidal cells, or through the cribriform plate of the ethmoid bone. Suppuration, compression of the brain, coma, and death, are the results to be looked for.

A remarkable illustration is recorded by Samuel Cooper as having come under observation at St. Bartholomew's Hospital. The patient suffered from an enormous polypus, which occupied both nasal fossæ. The eyes were four inches apart, and the left eye was absolutely blind. Paralysis supervened fifteen days before death, which followed a period of coma. On post-mortem examination, it was found that a portion of the growth almost as large as an orange was within the skull. The anterior lobe of the left hemisphere of the brain was almost entirely destroyed.

These growths are much more frequently met with in males than in females. They may occur at almost any age, but are most common in young people.

As already indicated, these growths not only give rise to considerable disfigurement and severe suffering, but sooner or later may prove fatal in result. Death may ensue from exhaustion caused by repeated hæmorrhage, constant discharge, disturbed sleep, and inability to take sufficient food; or from slow or even rapid asphyxia; or from implication of the nervous centres.

Treatment.—Complete extirpation of the growth by operation is the only treatment upon which any reliance can be placed.

In some rare instances, it is true, naso-pharyngeal polypi have spontaneously sloughed away. In the case of a young woman in St. George's Hospital, Mr. H. O. Johnson proposed to divide the soft palate, and endeavour to remove the whole growth from the pharynx; when, fortunately for the patient, the morbid tissue was attacked by rapid sloughing, which so entirely removed it, that no trace could be discovered of any part remaining.⁴

A somewhat similar result occurred in the case of a boy under the care of Mr. Birkett, in Guy's Hospital. In this case it was proposed to extirpate the polypus after removal of the upper jaw; but the parents would not consent. On one occasion hæmorrhage took place to such an extent as to render necessary the application of a ligature to the common carotid artery. The tumour subsequently sloughed, and the whole came away through a large opening in the cheek. Seven years afterwards the patient was quite well. The sinus in the cheek had healed up. There was no recurrence of the growth.⁵

Instances are also recorded by Saviard,⁶ Bonnet,⁷ Vimont,⁸ and others.⁹ But so fortunate an issue is far too rare to justify the expectation of its occurrence.

⁸ Quoted by Brevet, *Des Polypes naso-pharyngiens*, p. 16. Paris, 1855.

⁹ See the treatises by Robin Massé and D'Ornellas, already referred to.

In some cases the growth can be twisted off its base by forceps introduced through the anterior nostril or the pharynx; or it may be possible to pass the wire of an écraseur round the root of the tumour and thus remove it, either by tightening the wire or by using it as a galvano-cautery.¹

Occasionally also it may be practicable to detach the polypus by the forefingers introduced simultaneously into the anterior and posterior nostril, the tumour being then pushed forwards and backwards until it comes away.

There are, however, but few cases of fibrous polypus to which these methods are applicable. In most instances, the size of the growth, the position of its attachments and its extension into adjacent cavities, render necessary some surgical operation by which more free access is given to it than is possible through the natural openings. It is usually found most convenient to reach the tumour from the front, either by Rouge's operation, described at page 643, or by dividing one nostril at its junction with the cheek, or by the removal or temporary displacement of the whole or part of the upper jaw.

It is possible also to reach the growth from below by division of the palate, as recommended by Nélaton.² But this method has the obvious disadvantage that the growth is attacked at the part which is usually farthest from its origin.

Rouge's operation seems to me to be excellently adapted to many of these cases, and has the recommendation that it leaves no visible scar.

In some cases it suffices to open up the nostril by dividing the ala at its junction with the cheek, then cutting through the bones in the same direction, and turning up the side of the nose towards the middle line.³ If the tumour has attained a large size, and has extensively invaded the adjacent cavities, it is best dealt with by removal of the upper jaw.

Ablation of the upper jaw to facilitate the removal of a naso-pharyngeal polypus appears to have been first suggested by Whately, and first practised (though with incomplete success) by Syme, in the year 1832. To continental surgeons, however, is due the credit of having fully established the practicability and the value of this operation.⁴ It is now generally recognised as a legitimate and successful surgical procedure. Mr. Tatum appears to have been the first in this country to have operated with successful results.⁵

The various operative proceedings for the total or partial resection of the upper jaw will be found described in the essay on DISEASES OF THE MOUTH.

It fortunately happens that, in most cases partial resection of the maxilla suffices to afford the requisite space. The floor of the orbit,⁶ and even the dental arch, may be left intact.⁷

A good example of partial resection of the maxilla for the removal of a naso-pharyngeal polypus is recorded by Mr. Pick as having come under the care of Mr. Holmes in St. George's Hospital⁸ in the year 1866. The patient (a man), twenty-seven years of age, suffered from characteristic symptoms. The operation was commenced by a single incision from the inner canthus of the eye, down the side of the nose, and continued through the upper lip in the mesial line. The flap having been dissected up, the bone was first divided by a key-hole saw through the malar tuberosity: the bone was then divided into two, leaving the floor of the orbit, by the bone forceps, carried along the lower margin of the orbit. The other attachments having been divided in the usual manner, and the bone having been severed from the soft palate, it was easily removed, and the origin of the tumour from the base of the skull exposed. The polypus was now grasped, and easily extracted. . . . The flap was readjusted. . . . There was very little bleeding during the operation. . . . The man

⁸ *St. George's Hospital Reports*, vol. ii. p. 162.

made a good recovery, and left the hospital with the wound quite healed, five weeks after the operation.' The growth recurred, and was again removed eight years after the original operation.¹ He has since remained free from any return of the disease, and was seen a few weeks ago in perfect health. The polypus on both occasions was of a purely fibrous structure.

These operations upon the upper jaw, and the removal of vascular polypi from the base of the skull, are sometimes attended with a good deal of hæmorrhage, so that there is some danger, if the patient is under the influence of an anæsthetic, of blood entering the trachea. If the tumour is very extensive and vascular, it may be therefore worth while to perform tracheotomy as a preliminary precaution, though with efficient assistance this is not often necessary. A thin flat sponge tied to a string, and pressed against the floor of the nose and back of the pharynx, will be found useful.

But the safest plan is of course to dispense with an anæsthetic, if the patient will allow the operation to be performed without it. Mr. Holmes has referred to three cases,² one of which occurred to myself, in which the patient has suffered the operation of removal of the upper jaw without an anæsthetic. Another method is the 'osteoplastic' operation of Langenbeck³ by which the soft parts and the bone are divided along the same lines, which are those for the ordinary resection of the jaw, excepting that the connections of the nasal and frontal bone to the maxilla are left undivided; the jaw and its coverings are then turned inwards and upwards, and the tumour removed from behind, after which the parts are replaced and fixed by deep sutures.

By whatever operation the polypus is exposed, great care must be taken to remove it as completely as possible. The actual cautery should be at hand, not only for the arrest of bleeding, but also for the destruction of any portion of the root of the tumour which may remain adherent to the periosteum.

MALIGNANT POLYPI.

The various forms of sarcomata and carcinomata are met with in the nasal cavities, sometimes growing directly from their walls, in other cases invading them from a neighbouring origin.

They generally occur either in young children or in old persons.

Such growths not only expand, but infiltrate the tissues of the nose; they grow quickly, bleed on slight provocation, and give rise to foul discharge and much pain.

If recognised in the early stage, the tumour and its connections should be freely and widely extirpated. Of course there is great danger of a return of the disease, but life may sometimes certainly be prolonged by the operation.

If the disease be advanced, no operative proceedings are to be recommended.

CARTILAGINOUS AND OSSEOUS GROWTHS.

Cartilaginous growths are occasionally seen in the nose, and are almost always attached by a broad base to the septum. They cause inconvenience by blocking up the nostril and obstructing respiration, and are sometimes attended with troublesome sneezing and coryza. The few cases I have seen have all been in young people.

The growth is easily removed by the knife or scissors.

Exostoses springing from some part or other of the nasal parietes, or from some neighbouring bone, may invade the cavities of the nose, and give rise to symptoms more or less resembling those produced by other growths. The degree of hardness and fixity presented on careful exploration establishes the diagnosis. Very considerable disfigurement may sooner or later result.

In some cases cartilage in variable proportion, and variously disposed, enters into the formation of growths of this kind.⁴

² Holmes, *Surgery, its Principles and Practice*, p. 502.

³ *Deutsche Klinik*, 1861, p. 281; and Schmidt's *Jahrb.* vol. cxliii. p. 195.

⁴ A remarkable case of this kind is related in *Guy's Hosp. Reports*, ser. i. vol. i. p. 403.

Besides these exostoses, there is another kind of osseous tumour occasionally met with in the nasal fossæ and sinuses¹ of the face, which seems to originate from the mucous or periosteal lining of these cavities, rather than to grow like a true exostosis from their bony walls. These tumours, which may attain a large size, and produce great disfigurement, usually have their origin in the frontal sinuses or in the nasal fossæ; but they are prone after a time to become separated from their attachments, and are found loose in the containing cavity.

Their removal is to be accomplished by such operative measures as are necessary for the exposure of the cavity in which they are contained.

DISEASES OF THE LARYNX.

IN Laryngeal Diseases the ordinary symptoms, such as pain, cough, difficulty in breathing and in swallowing, alteration of the voice, &c., often fail to indicate precise nature and seat of the malady.

Moreover, irritation of or pressure upon the recurrent or other nerves by tumours, aneurisms, &c., as well as certain morbid conditions of the nervous system generally, may give rise to symptoms which more or less closely simulate those produced by actual disease of the larynx itself. Hence it constantly happens that some aid to diagnosis must be obtained, or the treatment adopted is likely to be as unsuccessful in result as it is necessarily uncertain in direction. Such aid is afforded by the Laryngoscope. This instrument was suggested—indeed repeatedly suggested—many years ago, but it has only recently come into general use. Its great value as an aid in the diagnosis and treatment of diseases of the larynx, though fully established, was not yet generally recognised and appreciated when the First Edition of this work was published.

Historical details relative to the invention of the laryngoscope would be altogether out of place in these pages.¹ It may, however, be stated that Dr. B. G. Babington appears to have just claims to be considered the first successful laryngoscopist.² Further, it is impossible to omit an expression of grateful acknowledgment of the labours of Professor Czermak, formerly of Pesth.³ To him, probably more than to any one else, we are indebted for the earliest complete demonstration of the general practicability and value of laryngoscopical examinations, and the best methods of making them, and still more, perhaps, for the disinterested and painstaking manner in which, both on the Continent and in this country, he has published his results, and personally taught his method.

LARYNGOSCOPY.

The Laryngoscope essentially consists of the laryngeal speculum, together with some contrivance, by means of which a good light can be thrown upon it, when introduced into proper position in the pharynx.

The laryngeal speculum is a small plane mirror, fixed to one extremity of a slender but strong stem of sufficient length. The other extremity of the stem is fitted into a light handle, either permanently or in such manner that it can be removed or changed at will. The mirror may be of polished steel, speculum metal, or silver; or it may be made of silvered glass (looking-glass), mounted in a thin

¹ The history of Laryngoscopy is more or less completely discussed in the following works:—*The Use of the Laryngoscope*, by Morell Mackenzie, M.D., 3rd edit. London, 1871. *The Laryngoscope in Diseases of the Throat*, by Sir (t. D. Gibb, M.D., 3rd edit. 1868. Art. by Mr. Windsor in the *Med.-Chir. Review*, Jan. 1863. Art. 'Laryngoscope' in the *Dictionnaire des Sciences médicales*. Paris, 1868. *Klinik der Krankheiten des Kehlkopfes*, by Dr. Ludwig Türck. Wien, 1866. *Die Laryngoskopie*, by Dr. Bruns. Tübingen, 1865. *Lehrbuch der Laryngoskopie*, by Dr. Tobold. Berlin, 1863. In these works may also be found much valuable information relative to the construction and practical uses of the laryngoscope, as well as to the diagnosis and treatment of Diseases of the Larynx. Constant reference has been made to them in preparing the following pages.

² *London Medical Gazette*, vol. iii. p. 555. London, 1820.

³ *Zeitschr. der Ges. der Aertze*, No. 17. *Der Kehlkopfspiegel und seine Verwerthung für Physiologie und Medicin*. Leipzig, 1860. *Das Laryngoscope*. Paris, 1860. A translation of this work was published by the Sydenham Society in 1861. Also many subsequent contributions to Foreign and British journals.

metal frame. The metallic mirrors are readily warmed, retain their heat well, and are so thin as to occupy but little space. On the other hand, the silvered glass mirrors are much less liable to get tarnished or scratched; no practical disadvantage arises from their comparative thickness, and there is no difficulty in keeping them of such temperature as to prevent the deposition of moisture upon the ~~them~~. They are, therefore, as a rule to be preferred.

In shape the mirror may be circular, ovate, elliptical, or quadrilateral with rounded angles. The three first-named forms are recommended by Türck,¹ the last by Czermak.² For all ordinary examinations the circular and quadrilateral forms are the best, and they answer equally well. In cases, however, in which it may be necessary to carry the speculum deeply into the pharynx, or in cases in which the tonsils are much enlarged, the ovate or elliptical form is preferable.

The mirrors ordinarily supplied by the makers vary in diameter from half-an-inch to an inch or more. In every case the larger the mirror that can be employed the better is the general view obtained. The stem should be straight, or only slightly curved, and four or five inches in length. It should form with the diameter of the mirror drawn to its point of junction an angle of from 120° to 125°. Moreover the mirror should be so inclined as to look somewhat downwards when the stem is held horizontally. It is advantageous to have the stem of such material that it may be bent in one direction or the other, so that different degrees of inclination may be given to the mirror according to the requirements of the case under examination.

For the illumination of the speculum when in position either direct or reflected light may be employed. But in either case, if the light should not be very powerful, concentration of the rays is desirable.

Direct sunlight answers perfectly, but is seldom available. Some other source of light *must* frequently, and *may* always be employed. Diffused daylight is rarely, if ever, sufficiently powerful.

The source of light is placed on one side of and somewhat behind the head of the patient, who should, if practicable, be seated near the corner of a table. The rays are then reflected from and concentrated by a circular concave mirror duly arranged immediately in front of the face of the surgeon. The mirror should be three or four inches in diameter, and should have a focal distance of about twelve or fourteen inches. It may be perforated or not in the centre. If perforated, it may be placed in front of one eye, and the view may be taken through the perforation. The hole in the centre should be oblong, its edges corresponding to the eyelids, so that its long diameter is transverse. If not perforated, it may be arranged in front of the forehead and nose, and between the eyes; or lower down in front of the nose and mouth. In either of these arrangements both eyes may be used; in the former looking below, in the latter above the reflector. The perforated reflector should theoretically give the more perfect view. But practically the imperforate reflector is found to be as efficient in all ordinary cases; and it possesses the great advantage of permitting the equal use of both eyes. The reflector may be held in the hand, when the hand is not required for any other purpose; or it may be supported on a stand in such a manner as to be freely movable in all directions. In Tobold's arrangement it is connected with the stem of the lamp, or the light-concentrator. Generally, however, it is attached to the head of the surgeon by means of a strong spectacle frame, an elastic frontal band, or a steel spring passing over the vertex. The first method is best adapted for the perforated reflector; the second for the imperforate reflector in front of the forehead; and the third if the reflector is worn lower down. Czermak's original plan of fixing the stem of the reflector at right angles to a piece of wood to be held between the teeth may be considered obsolete. In any case the reflector should be connected with its support either by a ball and socket joint, or in such other way as permits it to be turned easily in any required direction.

As a source of light, any lamp which burns with a bright, steady, full-bodied

¹ *Méthode pratique de Laryngoscopie*, par le docteur Türck. Paris, 1861; and *op. cit.* p. 38.

² *Des Laryngoscope*, par le docteur Czermak. Paris, 1860.

flame, may be employed. A good moderator or reading lamp; or an Argand gas-burner, answers perfectly well for all ordinary purposes. But it is desirable to have the lamp so arranged that it can be raised or lowered in position, and moved from side to side. Mackenzie's 'rack movement laryngoscopic lamp,'¹ which readily admits of perpendicular and horizontal movement, is admirably adapted for use in the consulting-room.

The light of the lamp may be advantageously concentrated by means of one or more lenses placed in front of the flame, and a concave reflector or white reflecting surface placed behind it. Of all the so-called 'light concentrators' which I have seen, I believe Mackenzie's is the best for ordinary use. It consists of a metallic cylinder having a short branch which bears a plano-convex lens two or three inches in diameter. The cylinder replaces the glass chimney of the Argand gas-burner; and its branch is so situated, and of such dimensions, that the lens is opposite the middle of the flame, and receives and concentrates a large body of luminous rays.

The general arrangements for making an ordinary laryngoscopic examination by means of the reflector and artificial light are represented in fig. 146.

The lamp, the mouth of the patient, and the eyes of the observer should be as nearly as possible in the same plane. If the laryngeal speculum is held in the right hand of the surgeon, the lamp should be placed on the right side of the patient, and

FIG. 146

vice versa. If, as may sometimes be convenient, the lamp is placed above and behind the head of the patient, the vertical plane must be preserved; but the speculum may be held with equal advantage in either hand without risk of obstructing the light.

The patient should, if possible, be comfortably seated opposite the surgeon in a nearly erect position. His body should lean somewhat forwards, and his head should be inclined slightly backwards, but should not be thrown so far back as is often done. Sometimes it is advantageous to employ a 'head-rest,' which may either be fixed to the back of the chair, or may have a separate stand. When in proper position, the patient is directed to open his mouth as widely as possible, and to breathe quietly but deeply. His tongue may be protruded, and held by himself or by the surgeon, the fingers and thumb being covered by a soft towel or handkerchief to prevent slipping; or it may be kept within the mouth, and gently pressed forwards against the lower teeth, an attempt being made at the same time to depress and flatten or render concave its posterior part. Sometimes one plan, sometimes the other is found to be the more effectual. Meanwhile the surgeon arranges his reflector so as to throw the light into the open mouth of the patient. When he has succeeded in illuminating the middle of the soft palate, the uvula, and posterior pharyngeal wall by a bright disc of light, he may proceed to introduce the laryngeal speculum.

The handle of the speculum should be held somewhat 'pen-like' between the

¹ Made by Mayer and Meltzer.

thumb and the fore and middle fingers of one hand or the other. The speculum should be slightly warmed previous to its introduction, either over the lamp by momentary immersion in hot water, in order to prevent deposition of moisture upon its surface.¹ Care must be taken, however, that it is not made too hot. Its temperature may be easily tested by the hand or cheek of the surgeon. The speculum should be introduced with its reflecting surface directed downwards, and forwards. It should be carried backwards through the cavity of the mouth, deliberately, confidently, and steadily, and then applied with gentle but firm pressure against the uvula and neighbouring portions of the soft palate. Uncertain, hesitating, and hasty movements of the instrument are liable to give rise to objectionable titillation. In its passage through the mouth, it should not come in contact with the tongue, nor, indeed, with any other parts than those against which it is to be placed. As a rule, it should not be carried so far back as to touch the posterior pharyngeal wall. Sometimes, however, especially in certain exceptional cases, this may be done with considerable advantage. The hand of the surgeon must be kept somewhat down and well towards its own side, so as not to obstruct the light. The third and fourth fingers may rest against the chin or cheek of the patient. The stem of the instrument should lie in or near to the corresponding angle of the mouth. In a large proportion of cases, no difficulty is encountered, and the patient suffers comparatively little inconvenience.

When the speculum is thus placed in position and well illuminated, it exhibits to the surgeon images of those parts of the larynx upon which the rays reflected from its surface are made to fall. It must be borne in mind, however, that as a necessary consequence of the position of the mirror in relation to the eye of the observer on the one

hand, and to the larynx of the patient on the other, the parts appear in the image as though reversed antero-posteriorly. And they are thus conventionally represented in all ordinary laryngoscopic diagrams.

This so-called 'reversal' or 'inversion' of the image is illustrated by fig. 147, in which B diagrammatically represents the parts as seen when simply looked down upon, and A the same parts as they appear reflected in the mirror. No practical difficulty or inconvenience results from this apparent inversion.

By varying the inclination of the mirror, and slightly changing its position from time to time, the following parts, or rather certain portions of them, may be succes-

FIG. 147.—Diagram illustrating the antero-posterior reversal of the laryngoscopic image.

The small excrescence situated on the right vocal cord (B) might be falsely supposed to be on the left from the appearance presented in the mirror (A).

¹ Various expedients have been suggested with a similar view. Thus, Dr. H. G. Wright contrived a speculum, the temperature of which was maintained by a wire placed behind the mirror and heated by galvanic action. Dr. Buzzard recommends that the surface of the mirror should be covered with a film of glycerine. But no plan answers better than the simple one above-mentioned; nor is any other so easy of application.

sively brought into view; the base of the tongue and glosso-epiglottidean ligaments; the epiglottis and aryteno-epiglottidean ligaments; the cartilages of Santorini, and the arytenoid cartilages; the true and false vocal cords; the ventricles and anterior wall of the larynx, including a portion of the cricoid cartilage; more or less of the anterior wall of the trachea; and if the glottis is very widely open and the light very good, even the bronchi appearing as two dimly defined dark circles, and more rarely a small portion of the cavity of the right bronchus. These several parts, however, cannot all be seen with equal facility. Numerous rules have been laid down as to the position and degree of inclination of the mirror best adapted for the special examination of each particular part.¹ But it is needless to repeat them. A correct

knowledge of the relative positions and natural appearances of the parts, and a consideration of the simplest laws of catoptrics, together with a certain amount of practical experience, will enable the laryngoscopist to bring into view and recognise one part after another so far as may be practicable. Repeated attempts are often necessary before even partial success can be attained. And sometimes even the utmost perseverance only results in failure. But this need rarely happen. The possible sources of difficulty are numerous, and the actual difficulties may be great; but they may generally be obviated or overcome, at any rate to some extent, by patience and judicious management. Those who suffer from chronic laryngeal affections are, as a rule, the best subjects for laryngoscopic examination—not the worst, as might be sup-

posed. Their desire for benefit affords a stronger stimulus to patience and self-control than can actuate the healthy; and, moreover, they are usually already accustomed to expose their fauces for inspection, and to submit to local applications, by which indeed the normal sensitiveness of the parts may have been diminished.

The most common sources of difficulty are as follows: general nervousness and excitability of the patient; fancied or real inability on his part to open his mouth sufficiently widely, and awkwardness in the management of his tongue; relative largeness, or some swollen condition of the tongue; malformation or deformity of the soft palate and neighbouring parts from ulcerative disease, and subsequent contraction of cicatrices; elongation and thickening of the uvula; enlargement of the tonsils; pendency of the epiglottis; and, lastly, extreme sensitiveness of the uvula and soft palate, either natural or resulting from existing inflammation or ulceration.

Difficulties arising from the first three sources may be overcome almost invariably by patience and judicious management on the part of the surgeon, and a little practice on the part of the patient. Hastiness in manner and in method of proceeding should be avoided; and every effort should be made to encourage, reassure, and inspire confidence. By his own example the surgeon should show the patient how to open his mouth, and should demonstrate the slightness of the inconvenience caused by the introduction of the speculum. If proper directions are given, and the patient is induced to practise occasionally by himself before the looking-glass, he will probably return in the course of a few days comparatively well able to display his fauces, and to submit to the needful examination.

By one or other of the methods already indicated (p. 658) the tongue may generally be kept out of the way. If, however, these methods fail, and the tongue still rises so high as to obstruct the view of the soft palate, &c., the patient should be directed to make a few deep inspirations, and alternate them with the repeated pronunciation of the broad vowel 'a' (ah). He should breathe through the mouth only; not through the nose. In this way the tongue may often be brought into favourable position. Sometimes a broad spatula or tongue depressor may be advantageously

¹ Krishaber, Art. 'Laryngoscope,' in *Dict. encyclop., op. cit.* p.*497 et seq. Türk, *op. cit.* and *Méthode pratique de Laryngoscopie.* Paris, 1881.

used. But, as a general rule, the introduction of any unnecessary instrument into the mouth should be avoided.

Occasionally by sliding the finger along the tongue (the speculum being at the same time introduced and illuminated), an effort at vomiting is produced, during which the tongue being depressed and the larynx raised, a good though momentary view may be obtained.

In cases in which *the soft palate is unusually short, and the uvula small and thin*, the speculum is apt to slip up somewhat behind them, and to become partially hidden. Under such circumstances it is better to hold the instrument as nearly as possible in its proper position, without touching or resting against the soft palate.

An elongated and thickened uvula may obscure the view by hanging below, and turning round the inferior border of the speculum. The employment of a larger speculum, or a little manœuvring of the instrument, serves to obviate this source of difficulty for the time being; and it may be permanently removed by appropriate measures.

Considerable embarrassment is often caused by *chronic enlargement of the tonsils*. In such cases a narrow, elongated, elliptical speculum should be used, and carried somewhat more deeply into the pharynx than is usually necessary. Enlarged tonsils are often so little sensitive that the speculum may be pushed well in between them without causing much discomfort.

Pendency or projection backwards of the epiglottis is a frequent source of considerable difficulty. Gibb states as the result of his observations that some such abnormal condition is to be found in eleven per cent. of otherwise healthy individuals.¹ It depends upon undue elongation of the glosso-epiglottidean ligaments or folds of mucous membrane, together with relaxation or weakness of the muscular fibres they contain. The degree of obliquity observed varies greatly in different cases, and to some extent in the same case under different conditions. In some instances the epiglottis hangs almost horizontally over the entrance to the larynx; but more frequently its deviation from the normal erect position is comparatively slight, or even only occasional. Laryngoscopic inspection is of necessity proportionately impeded. The greatest difficulty is often experienced in obtaining a satisfactory view, and sometimes even partial success appears to be impossible.

In all cases of pendent epiglottis, it is necessary to carry the speculum further backwards and downwards, and to make its reflecting surface look more forwards than is desirable in the normal condition of parts. Sometimes its lower border must be placed against the posterior wall of the pharynx. When the speculum is in position, the patient should be directed to utter a series of short, high *staccato* notes, or to imitate a shrill *falsetto* laugh. During the emission of such sounds the epiglottis is suddenly raised, and jerked forwards. Opportunity may be thus afforded for a succession of brief glimpses of the interior of the larynx, which may suffice at any rate to determine the diagnosis. Another method which sometimes proves partially successful is as follows. The head of the patient is thrown back as far as possible, and his tongue is projected and held by himself. The speculum is introduced and inclined slightly backwards and downwards, and the surgeon having lowered his head, looks into it as it were from below upwards. At the same time with his free hand he presses the pomum Adami of the patient backwards and somewhat upwards.² There can be no doubt that the larynx may often be moved into a comparatively favourable position for inspection by external manipulation; but the method is liable to occasion much discomfort, and sometimes considerable pain.

In some instances, in spite of all attempts, the epiglottis still persistently hides the larynx from view. And in such cases it may be desirable to raise it mechanically by instrumental aid. Forceps, tenaculums, and hooked sounds of various kinds have been devised for this purpose by Bruns,³ Voltolini, Fournié, Lewin, Mackenzie and

¹ *Op. cit.* p. 44.

² See Krishaber, *op. cit.* p. 493.

³ Bruns appears to have been the first to have used an instrument of this kind; and he did so in the case of his own brother, who suffered from a polypoid growth in the larynx. The

others. But all such instruments are difficult for the surgeon to use, and still more difficult for the patient to tolerate. It is only in very exceptional cases that they can be employed with advantage. The epiglottis is extremely sensitive; but it bears firm pressure and a steady but gentle pull better than the uncertain titillation of a hesitating touch. If any attempt at seizure be made, the instrument should be carefully warned previous to introduction.

Difficulties arising from unusual sensitiveness of the uvula and soft palate may generally be overcome by patience and dexterity on the part of the surgeon, and a little practice on the part of the patient. During the earlier attempts the speculum should not be maintained too long in contact with the parts. It should be at once withdrawn if decided retching is produced; and, short of such effect, if the irritability is great, it is better to apply the speculum repeatedly for a moment or two, and remove it as often, without caring to obtain any view until the parts have become as it were accustomed to the presence of the instrument. When once efforts at vomiting have been excited, there is little probability of success until a future occasion. The practitioner should remember that local congestion is often produced at the time, and might mislead unless he be on his guard. Preparatory measures of various kinds have been from time to time suggested; some of these are probably useful; others have been proved by experience to be altogether useless. Many owe their accredited efficacy to the confidence with which their exhibition has inspired the patient. The internal administration of bromide of ammonium or bromide of potassium in full doses has been strongly recommended and extensively tried, but with variable results. Gargles containing bromide of ammonium are said by Gibb to produce 'moderate anæsthesia' of the fauces in twenty-four hours.¹ Türk reports favourably of the repeated application to the fauces of a mixture (recommended by Bernatzik) which consists of three grains of hydrochlorate of morphia, one drachm of alcohol, and half an ounce of chloroform.² But all such applications as this would appear more likely to inflame than to soothe the sensitive parts. Alum gargles, or solutions of alum or some other astringent in the form of spray, are often useful. Occasionally a few whiffs of chloroform may be advantageously inhaled. But by far the best and easiest plan, so far as I know, is to direct the patient to suck a little ice immediately before submitting his throat for examination. The result is generally satisfactory.

Besides the various sources of difficulty thus discussed, there are others which depend upon inexperience and want of dexterity on the part of the surgeon. These can only be obviated by careful practice. The surgeon should not only familiarise himself with the management of the laryngoscope, but also with the relations and appearances presented by the healthy living parts when viewed by its aid. In colour especially, the mucous membrane of the larynx seen during life in the laryngeal mirror looks very different to what it does when examined after death on the *post-mortem* table. It is very possible for the tyro in laryngoscopy to mistake the natural tint of some parts for a certain degree of inflammatory redness.

The general appearances and relations of parts as seen in the laryngeal speculum need no special description. They may be learnt by the careful study of a larynx removed from the body, or by *auto-laryngoscopy*, or by the examination of the larynx of some living subject. But with regard to the colour presented by the different parts in a state of health, the following observations may be made.

The lingual surface of the epiglottis appears of a yellowish or pinkish drab colour. Its upper border is decidedly yellow. Its laryngeal surface, especially the 'cushion,' varies from a pinkish yellow to a deep pink; sometimes it appears bright red—^{so} bright, indeed, as to suggest the idea of the existence of an inflammatory condition. The aryteno-epiglottidean folds are pale pink. Stoerk accurately describes them as being about the same colour as the gums. The mucous membrane covering the arytenoid cartilages is still pink, but of a somewhat deeper tint. The false vocal

epiglottis was elevated by means of a pair of flat-bladed forceps, and the growth was successfully removed. See *Die erste Ausrottung eines Polypen in der Kehlkopföhle*. Dr. Bruns. Tübingen, 1862. Also *Die Laryngoskopie*. Dr. Bruns. Tübingen, 1865, p. 257.

¹ *The Laryngoscope in Throat Diseases*, op. cit. p. 46.

² *Allgem. Wiener Med. Zeit.* p. 98. 1863.

cords are perhaps slightly deeper pink still. The true vocal cords are distinguished by their glistening pearly whiteness; but sometimes they are slightly greyish. The cricoid cartilage is recognised by its well-marked yellowness. The tracheal cartilages appear of a yellowish drab colour; and between them the mucous membrane is pale pink.

A great variety of different instruments have been devised from time to time for the several purposes of demonstrating to others the appearances of the larynx under examination; of holding the laryngeal mirror in a position so as to leave both hands of the surgeon free; and of depressing the tongue at the same time the laryngeal mirror is introduced. Some of these are useful; others are rendered unnecessary by the aid of a skilful assistant. For descriptions of all such contrivances reference may be made to the special treatises already quoted.

GENERAL REMARKS ON THE TREATMENT OF DISEASES OF THE LARYNX.

The laryngoscope affords most valuable aid, not only in the diagnosis, but also in the treatment, of the various diseases of the larynx. Guided by the view obtained, the surgeon is enabled to make such local applications as may seem desirable, with accuracy and precision, and to perform many different operations—such as scarifying the mucous membrane, opening abscesses, removing growths, &c., with certainty and safety. The use of the laryngoscope has altogether set at rest the doubts formerly entertained as to the practicability of introducing brushes, probangs, and other instruments into the larynx.¹ Such doubts in the past time unquestionably prevented the adoption of methods of treatment that, in many cases, might have been eminently successful. But now-a-days it would appear that the danger is in the opposite direction, and that the tendency is rather to carry out local treatment too vigorously, or to rely upon it too exclusively.

Remedial applications may be made to particular parts, or to the whole of the interior of the larynx, with variable advantage by several different methods. It appears desirable to give at once a general description of such methods, and to refer in the succeeding sections to the special modifications requisite in the treatment of each particular malady.

Solid substances may be applied either in the mass or in powder. If applied in the mass, some form of caustic holder is requisite. No instrument answers so well, and at the same time is so safe, as a piece of moderately thick aluminium or silver wire mounted in a slender handle, and hollowed into a tiny cup, or roughened at the extremity. The roughened extremity may be dipped into various substances, as nitrate of silver, chloride of zinc, &c., while in a state of fusion; and a sufficient quantity may be taken up in a bead-like form, or as a thin coating. The wire may be easily bent at any angle requisite, and there is no danger of any considerable portion of the substance breaking off and falling upon parts it was not intended to reach. Such danger might arise during the use of some of the various complicated caustic holders that have been devised for similar purposes. By aid of the laryngoscope a small caustic bead, prepared in the manner described, may be definitely applied to any particular point; or if the wire is coated to a sufficient extent, the general surface may be wiped over.

Powders can only be applied to the mucous membrane generally. They may be inhaled through a tube, as recommended by Fournié, or, far better, blown in by means of Rauchfuss's insufflator,² or some modification of it. The insufflator, duly charged, is introduced into the back of the fauces, with the extremity turned down towards the larynx. The patient is then directed to make a slow, steady inspiration, and while he is doing so the india-rubber ball of the insufflator is suddenly compressed. In this instrument, however, the sudden pressure of the thumb is apt to alter its direction, and the application is not always certain. The tube insufflator is prefer-

¹ See edition of this Work, 1862, vol. iii. pp. 246 and 247, note.

² This instrument is figured in the essay on DISEASES OF THE NOSE, p. 645.

able, by means of which the operator blows the powder into the larynx. Under such circumstances, it is obvious that a considerable portion of the powder must be diffused over the mucous membrane of the larynx. The powders that have been used with most advantage in this matter are tannic acid, alum, acetate of lead, carbonate of bismuth, iodoform, and morphia ($\frac{1}{8}$ to $\frac{1}{2}$ gr.), and in some exceptional instances, nitrate of silver. It is scarcely needful to add that in every case the substance used should be very finely pulverised. Sometimes it may be advantageously diluted, or its bulk increased with two or three or more parts of sugar of milk, gum, or, better still, starch.¹

Liquids, or substances in solution, may either be applied by means of a full-bellied camel's-hair brush (cut square or pointed), or small sponge, mounted on a properly curved aluminium or silver wire, or whalebone stem; or they may be injected in a shower from Gibb's 'laryngeal syringe,' or 'hand atomiser';² or they may be inhaled in the form of 'spray,' produced by one or other of the various instruments devised for the purpose. Strong solutions, especially those of a more or less caustic nature, should, as a rule, be applied by the brush. Among the more generally useful of such pigments may be enumerated those of nitrate of silver (ʒij. or ʒij. to ʒj. of distilled water), perchloride of iron (ʒj. or more of the liquor to ʒj.), pure carbolic acid (ʒss. or more to ʒj.), alum (a saturated or weaker solution), sulphate of copper (a saturated or weaker solution), &c. Glycerine or honey may be advantageously mixed with these solutions in considerable proportion, in order to give them viscosity, and render them more adhesive. Iodine (gr. xx.), iodide of potassium (gr. v.), and olive oil (ʒj.), form an application recommended by Dr. Marcet.³ The 'glycerinum acidi tannici' (B. P.) may also be used in some cases. By means of the brush, all such substances may be applied with a certain degree of precision to any particular part. In some instances even nitric acid, chromic acid, and other powerful escharotics have been thus applied to ulcers, warty growths, &c., with safety and advantage. At the moment the brush is to be introduced into the larynx, the patient should be directed to make a full deep inspiration in order to dilate the aperture as widely as possible. In cases in which the epiglottis is pendent, it is often very difficult to get the brush beyond it into the larynx. Under such circumstances the laryngeal syringe may be more successfully used, inasmuch as its extremity may be guided round, and made to raise the pendent valve to a sufficient extent.

The inhalation of 'atomised fluids,' or spray, in the treatment of diseases of the air-passages, though suggested long previously, was first shown to be generally practicable by Sales-Girón in the year 1858.⁴ Since then the great value of this method has been fully established, and various improvements have been from time to time effected in the apparatus employed.⁵ The 'spray-producers' at present in ordinary use consist of two tubes (Bergson's tubes) fixed at right angles to one another; of these, one, placed horizontally, is connected at its distal extremity with some apparatus, by means of which a strong current of air or steam can be continuously projected through it; and the other, placed vertically, dips into a bottle or other small vessel containing the medicated fluid. The proximal extremity of each tube is terminated by a very fine orifice, and the orifice of the former tube is immediately over that of the latter. When a current of air or steam is made to rush forcibly from the orifice of the one tube over that of the other, it causes the

³ *On Diseases of the Larynx*, by W. Marcet, M.D., p. 18. 1869.

⁴ See the elaborate Report by Poggiale read before the Académie de Médecine, Paris, January 7, 1863, and the discussion thereon. Also Dr. Beigel's treatise *On Inhalation*, London, 1866, in which are full details as to the history of this method of treatment, and descriptions of the different forms of apparatus devised.

⁵ Mackenzie especially recommends Mayer's modification of Matthieu's apparatus, which is worked by means of a pressure-pump, and acts on a different principle to that described above. The fluid is forced through a fine orifice and projected against the interior of a vulcanite 'drum.' It thus becomes broken up into a fine spray. *Op. cit.* p. 90.

medicated fluid to rise, and breaks it up as it issues, and diffuses it in an exquisitely fine spray. In Dr. Andrew Clark's well-known instrument (as well as in the various modifications of it adopted by different makers), air is employed, and the current is kept up by means of an india-rubber 'handball' bellows. All such instruments, however, though unquestionably useful, are far inferior, for several obvious reasons, to those in which a jet of steam is employed, as first suggested by Dr. Siegel of Stuttgart. The steam is derived from water contained in a small boiler heated by a spirit-lamp. Figs. 149 and 150 represent two very efficient modifications of Dr. Siegel's original pattern.¹

The use of this instrument involves no continuous exertion like the handball spray-producers: and what is of far more importance, the atomised fluid is mixed with and propelled by a current of warm steam instead of cold air. Dr. Solis Cohen's single-ball spray-producer is a valuable instrument. Dr. Mackenzie has pointed out that there is no advantage in having a continuous spray for the throat, as the spray cannot be continuously inhaled. Where dyspnoea exists, a strong current of air or steam is to be avoided. A great variety of different solutions, the strength being varied according to circumstances, may be advantageously inhaled in the form of spray. Among them may be especially mentioned the following—the

FIG 150.—Siegel's Steam Spray-producer on stand, with Beigel's face-screen attached

FIG. 149.—Simple form of Siegel's Steam Spray-producer.

medicament being in each case in about the proportions specified to an ounce of water:—Alum (gr. x. to gr. xx.), tannic acid (gr. i. to gr. xx.), perchloride of iron (gr. $\frac{1}{2}$ to gr. ij., or of the liquor 3j. to 3ij.), as 'astringents'; common salt or chloride of ammonium (gr. x. to gr. xxx.), chlorate of potash, borax, or iodide of potassium (gr. iij. to gr. x.), as 'alteratives'; and watery extract of opium (gr. $\frac{1}{4}$ to gr. $\frac{1}{2}$), hydrochlorate of morphia (gr. $\frac{1}{8}$ to gr. $\frac{1}{4}$), or fluid extract of hemlock or hyoscyamus (mij. to mx.), as 'sedatives' or 'anodynes.' Very weak watery solutions of iodine, and chlorine (or chlorinated soda), tar water, lime water, weak alkaline solutions, sea water, the saline waters of many mineral springs,² and other solutions too numerous to mention have also been largely used in different cases with variable

¹ These as well as other forms of this apparatus are made by Messrs. Krohne and Sesemann.

² 'In 1849 Auphan, of Euzet-les-Bains, originated the idea of atomising the mineral water by throwing a jet of the liquid against the wall of the inhalatory. After a short time the same system was adopted in Lamotte-les-Bains. But Sales-Giron first constructed at Pierrefonds an apparatus through which the fluid was subdivided into a fine mist, which was inhaled by the patients with great benefit.'—Beigel, *op. cit.* p. 6. At many of the Continental Spas arrangements are now made for the inhalation of the 'atomised' waters.

advantage. Sulphurous acid in spray has been very strongly recommended in the treatment of various affections of the throat and larynx by Dr. Dewar and others. But experience seems to show that great caution is requisite in the use of this material. Though doubtless beneficial in some cases, in many it has proved not only less efficacious, but far more mischievous than was anticipated. Solutions of nitrate of silver and other powerful metallic salts are unsuitable for application by means of the spray-producer.

Many substances may be inhaled with very great advantage in the form of vapour or gas. In various acute or sub-acute affections nothing is more soothing and beneficial than the almost constant inhalation of warm steam, either plain or charged with some narcotic or anodyne element. The 'hemlock inhalation' of the British Pharmacopœia is very useful; it is rendered less disagreeable and perhaps more efficacious by the addition of a pinch or two of fresh dried hops; or the hops may be infused alone in the hot water; or a portion of opium may be added; in some cases vinegar is useful and pleasant. In chronic cases, according to their nature, the vapour of turpentine, or some aromatic terebinthinate, as pine oil or iodine, or calomel, may be inhaled with very great benefit. For the inhalation of steam, plain or medicated, various so-called 'inhalers' have been devised. Among those ordinarily used may be mentioned Nelson's, Maw's 'double-valved inhaler,' Mudge's, and Beigel's made by Robbins. The two first named are furnished with pieces of sponge which are intended to be imbued with the medicament to be used; but practically it is far better to remove the sponges and to mix the medicament with the hot water. The two last inhalers involve somewhat more respiratory exertion on the part of the patient. But they have the advantage of acting on the 'hookah' principle; the air to be inspired passes through the fluid, and thus becomes thoroughly warmed and charged with vapour. But by far the most perfect inhaler yet devised is that made by Messrs. Maw under the direction of Dr. Mackenzie, and by him termed the 'Electric Inhaler.' The advantages of this apparatus are so obvious that it will probably to a great extent supersede those hitherto in use. Bird's inhaling pipe is worthy of mention, as likely to prove very useful for the exhibition of certain vapours, &c.¹

Scarification of the mucous membrane of the larynx may be practised with considerable advantage in many cases. The instruments requisite and the method of operating have been already described in the first volume of this work.²

In all cases, if practicable, the instrument (which must be very sharp) should be guided by the aid of the laryngoscope. Mackenzie's laryngeal lancet answers the purpose admirably; but it is somewhat complicated, and is not so likely to be at hand as the simple instruments recommended. Numerous punctures or short cuts may be made, if requisite, in different parts. There is very rarely much bleeding, and never, so far as I know, any more than is actually beneficial.

The direct galvanisation of the vocal cords is undoubtedly of value in many nervo-muscular affections of the larynx. The most efficient instruments for this purpose are the laryngeal electrodes and necklet of Mackenzie.³ They are so constructed that the current does not pass till the metal point or sponge is in contact with the vocal cords. The instrument is held in the hand between the thumb and second finger, and when the sponge has been placed in the desired position, the operator with his index-finger presses on the key in the handle, and the electric current passes through the larynx to the skin externally. At the same time the patient wears a necklet communicating with the other wire of the battery. The galvaniser may be applied several times at the same sitting, it being kept in for a few seconds each time, and he should be directed to count one, two, three, &c., at the moment the current is made to pass. Dr. Fauvet has so modified this instrument by uniting the two poles, in the same handle, that pressure on the key permits the current to pass between the two knobs. This arrangement limits the current—a great advantage where it is desired to galvanise a single muscle.

CATARRHAL LARYNGITIS.

Acute catarrhal laryngitis is not a very rare affection. It varies greatly in intensity, and consequently in the degree of danger to which it gives rise. It may occur at almost any period of life, but is most frequently met with in adults of plethoric habits.

Exposure to cold and damp, especially after prolonged exertion of the voice, or when the general powers are reduced by fatigue, or by disease such as typhoid fever, measles, small-pox, diphtheria, &c., especially when the throat has been implicated, are the most common causes. It is common, too, after chronic laryngitis following syphilis or tuberculosis.

As a rule the fauces are first affected, and the inflammation spreads with variable rapidity to the larynx. Sometimes, however, the malady commences in the larynx itself, and is confined to it, or it may implicate the trachea.

The earliest symptoms are those of an ordinary 'sore-throat.' The patient complains of dryness, soreness, and a sense of constriction about the upper part of the throat, and occasionally pain and difficulty in swallowing. The feeling of discomfort is constantly referred to the pomum Adami, or its immediate neighbourhood. Respiration is rarely impeded. The patient's voice becomes thick and husky; and occasionally he tries as it were 'to clear his throat' by a dry, harsh, or half suppressed cough; often the voice is altogether lost.

In some cases the symptoms increase in severity; and the patient becomes restless and anxious. The face is flushed, the skin hot and dry, the pulse hard and quick. Respiration becomes more and more seriously impeded. Inspiration is difficult, protracted, and painful, and is accompanied by a wheezing, whistling, or harsh throttling sound. The chest is not fully expanded; and there is diminution of the respiratory murmur. Expiration remains comparatively easy; for the warm, moist air from the lungs irritates the inflamed and sensitive mucous membrane much less than the colder, drier air, inspired from without. The dyspnoea is constant in so far as it depends upon constriction of the glottis from swelling of the mucous membrane; but it becomes greatly aggravated at intervals in consequence of spasmodic action of the muscles. The voice, at first husky and hoarse, soon becomes low in tone, or 'cracked' and uncertain, and finally is altogether lost, the patient speaking only in a whisper. In some cases there is but little cough. In others the cough is frequent, and harsh, husky, or stridulous in character. Cough may be provoked either during inspiration by the contact of cold dry air, or during expiration by the presence of little masses of secretion. The sputa in the earliest stages are very scanty, and consist of little more than saliva; later they become somewhat more abundant, but are still semi-transparent, though more or less tenacious and viscid, containing laryngeal mucus as well as saliva; still later they are opaque and greyish, and sometimes are slightly streaked with blood. After any of these have been coughed up a painful sense of rawness about the part is often experienced. The small, firm, agglutinated masses which are occasionally coughed up, probably come, according to Krishaber, from the ventricles of Morgagni. The difficulty of swallowing, almost invariably noticed as one of the earliest symptoms, in these severe cases becomes more and more pronounced as the malady progresses. '*Difficulty of deglutition* for which no adequate cause is visible in the fauces,' speedily followed by '*difficulty of breathing* for which no adequate cause can be discovered in the thorax,' are, in the words of Sir Thomas Watson, 'among the earliest of the symptoms that bespeak danger, and ought to excite alarm.'¹

If the malady advances to the next stage, and no relief is afforded, the general distress of the patient becomes intense. He labours and struggles for breath. His anxiety and restlessness are extreme. He cannot lie down; or, if exhausted, he tries to do so, he soon starts up involuntarily, gasping for very life. His countenance becomes pale and livid, or even ghastly; his eyes protrude; sweat pours from his forehead; his skin is cold and clammy; his pulse becomes weak and intermittent; exhaustion, drowsiness, and perhaps delirium supervene; and lastly, he dies suffocated

¹ *Lectures on the Principles and Practice of Medicine*, 5th edit. 1871, vol. i. p. 865.

either almost suddenly from spasm of the larynx, or by a process of comparatively slow asphyxiation. The morbid changes which give rise to the symptoms thus described may be traced during life by aid of the laryngoscope, or made out after death on post-mortem examination.

On *laryngoscopic inspection* the mucous membrane of the larynx is seen to be of an unnatural scarlet red colour, and more or less thickened or swollen, from serous or sero-fibrinous effusion into the areolar tissue. Occasionally superficial erosions may be recognised here and there; but neither deep nor extensive ulceration is observed, or only extremely rarely. The redness and swelling, as a rule, are especially manifest in those parts in which the mucous membrane is thick, and is supported by abundant loose submucous areolar tissue. Thus the aryteno-epiglottidean folds, the mucous membrane of the vestibule, the false vocal cords, and the laryngeal aspect of the epiglottis present these appearances in the most marked degree; and, generally speaking, they are affected in extent in the order in which they are named. The mucous membrane of the true vocal cords, on the other hand, being comparatively thin, and closely connected with dense subjacent tissues, is less swollen, and less uniformly reddened. Sometimes it is marked by red striae or patches. Sometimes it seems only to have lost its pearly whiteness, and to have become dull, clouded, or pinkish in colour, and somewhat unduly protuberant. But, as may readily be understood, in many cases the true vocal cords are almost or entirely concealed from view by the swollen parts above. Still more is this the case with the parts of the larynx below the glottis and the trachea, which, nevertheless, not infrequently suffer from extension of the inflammation. The epiglottis is usually seen to be erect, rigid, and swollen. It is consequently unfitted to fulfil its natural valvular office. Sometimes it may be felt by the fingers as a smooth rounded, 'cherry-like' intumescence. Occasionally it gives rise to sensations similar to those produced by the presence of a foreign body. The patient 'feels as though he had something in his throat.'

The condition of the epiglottis serves in great measure to explain the difficulty in swallowing, and the sense of suffocation often experienced when the attempt is made. The dysphagia is still further accounted for by the pain caused by the necessary movement of the inflamed and unduly sensitive parts.

The swollen condition of the mucous membrane and consequent constriction of the glottis manifestly give rise to the constant difficulty of breathing, and this as a rule is much more marked in children on account of the small area of the opening of the glottis, and also to spasm, which in them is much more easily induced. The temporary paroxysms of extreme dyspnoea are probably caused by muscular spasm incidentally or accidentally excited.

Post-mortem examination shows that the swelling depends upon an injected, infiltrated, and cedematous condition of the mucous membrane and submucous tissue. The redness of the parts observed during life is often partially or wholly lost—inasmuch as the mucous membrane shares in the general pallor of death. Soft, semi-purulent, or viscous exudation is usually found covering to some extent the membrane. In some cases the trachea and bronchi are also affected; and the lungs are congested, or even pneumonic.

The *diagnosis* of acute catarrhal laryngitis is not difficult. It may be distinguished from croup and diphtheria by the absence of the false membranes and fibrinous exudations which characterise these maladies; and from croup especially by the difficulty in swallowing and the early alteration or extinction of the voice. In croup swallowing is usually easy; the voice is often but little affected; the breathing is 'stridulous,' and the cough has a peculiar ringing 'brassy' sound.¹

Laryngitis may be distinguished from the first effects of a foreign body in the air-passages by the sudden severity with which in the latter case the dyspnoea comes on, the periods of intermission which occur, and the absence of premonitory febrile disturbance. The difficulty of breathing caused by the presence of a foreign body is usually most marked during expiration. The reverse is the case in laryngitis.²

¹ See the article on CROUP AND DIPHTHERIA.

² See chapter on 'Foreign Bodies in the Air Passages,' essay INJURIES OF THE NECK, vol. i.

In cynanche tonsillaris respiration is often obstructed. But the cause of obstruction is at once manifest on inspecting the fauces. In laryngitis, on the other hand, the amount of swelling in the upper part of the throat, if even any exists, is altogether insufficient to account for the extreme difficulty of breathing and swallowing, and the alteration or extinction of the voice. It must be borne in mind, however, that laryngitis, or at any rate oedema of the larynx, may coexist with inflammation of the tonsils and mucous membrane of the fauces and pharynx.

In simple pharyngitis there is little or no dyspnoea; but swallowing is painful and difficult, and pain is felt when the larynx is pressed backwards.

The *course* of acute catarrhal laryngitis is usually rapid. Its duration depends upon the intensity of the inflammation, the constitution of the patient, and the nature and efficacy of the treatment adopted. In the worst cases, if unchecked, it often proves fatal on the fourth or fifth day, and sometimes much more speedily. The celebrated General Washington died of this disease within twenty-four hours. Sir Thomas Watson alludes to an instance in which a fatal result ensued in twelve hours.¹

Mr. Gray mentions the case of a man who was 'admitted into St. George's Hospital complaining merely of a sore throat. He walked into the hospital, and seemed in such good health that he would not have been admitted, but for the circumstance of his having come some distance from the country. About three hours after his admission, the house surgeon was summoned in all haste to see him, as he was said to be dying of suffocation. He went immediately, but found the patient quite dead. Post-mortem examination revealed all the evidences of laryngitis, supervening apparently upon inflammation of the pharynx; but it was especially remarked, that the chink of the glottis was not much narrowed from oedema. In this case there can be no doubt that death was produced by spasmodic contraction of the muscles of the glottis.'²

In some instances, however, the malady runs a less rapid course, and the patient survives until the eighth or ninth day. In others, and these happily the majority, the inflammation subsides either spontaneously, or as the result of treatment. In such case the effects may disappear almost altogether with comparative rapidity, or the malady may assume a chronic form.

Treatment. The treatment requisite depends upon the severity of the malady, and the stage it may have reached. Measures which are urgently demanded in some cases are in others unnecessary, and even dangerous. And the mode of treatment that might be most efficacious at the onset of the malady, if adopted too late, may only hasten the fatal termination.

In the earlier stages, and in cases in which the symptoms are comparatively mild, perfect quiet in a warm moist atmosphere, soothing inhalations either of simple or medicated steam or spray, and the administration of salines, with perhaps antimonials and tincture of aconite or some sedative, according to circumstances, constitute the treatment requisite; astringent sprays of alum or sulphate of zinc (two to five grains to the ounce) are usually very beneficial; entire rest of the larynx is imperative. But in all cases careful watching is necessary; for dangerous symptoms may supervene at any time, and even almost suddenly.

In the more severe forms of the malady, similar but more energetic measures must be rigorously enforced. Soothing inhalations may still be advantageously employed, but their use must be more constant. Antimony and tincture of aconite in small but frequently repeated doses should be administered, especially in cases in which there is much general inflammatory fever.³ Free mercurialisation combined with opium or hyoscyamus has been strongly advocated, especially by the German surgeons, but its efficacy appears doubtful; and much precious time may be lost before the system can be affected.

Local blood-letting by means of leeches to the neck or suprasternal notch, or cupping to the nape of the neck, may sometimes prove beneficial. So also may blisters

¹ *Op. cit.* vol. i. p. 867.

² See first edition of this work, vol. iii. p. 226.

³ The following formula may be recommended:—Vin. antim. tart. mij. to mijj., tinct. aconiti mj to mijj., liq. ammon. acetat. ʒss.; to be taken in water or camphor julep every quarter of an hour or every half-hour, until some obvious effect on the circulation, &c. is produced, and then to be continued less frequently.

or milder counter-irritants; but these should not be applied immediately over the larynx.

When the mucous membrane is so swollen as to impede respiration and swallowing to a serious extent, scarification by means of a sharp-pointed guarded bistoury, or some specially designed instrument, is often followed by speedy relief.

A somewhat remarkable case illustrating the effects of this method of treatment came under Mr. Durham's observation in December 1806. 'A gentleman residing in Essex, fancying he heard poachers in the neighbourhood, got up in the middle of the night, went out carelessly dressed, and concealed himself for two or three hours in a ditch. The next morning he was seized with all the symptoms of intense laryngitis; and he died suffocated within eighteen hours. Three days afterwards the brother of this gentleman, depressed in spirits, and fatigued and almost exhausted, was exposed for some time to cold and wet. In the evening he was attacked by symptoms similar to those from which his brother had suffered. The next morning I saw him in consultation with his medical attendant, Mr. Jordison of South Ockenden. The soft palate, uvula, and pillars of the fauces were acutely inflamed, and very much swollen and cedematous. The epiglottis and aryteno-epiglottidean folds were in a similar condition. The patient's suffering was extreme; breathing was carried on with great difficulty; swallowing was impossible. I at once freely scarified the affected parts by a number of punctures and small incisions, and caused the patient to inhale the steam of hot water. A considerable quantity of serous or sero-purulent exudation with some blood was discharged. In the course of half an hour the breathing was much relieved, and swallowing was accomplished without any great difficulty. The swelling of the parts rapidly subsided, and the next day, when I saw him again, the patient could breathe and swallow with comparative ease—indeed, almost naturally—but he still suffered from considerable general distress, and symptoms of pericarditis were recognised. Death took place twelve hours after my visit, or about sixty hours from the commencement of the attack. Post-mortem examination revealed the most intense inflammation of the whole pericardium I have ever seen. But the extent to which the faucial and laryngeal mucous membranes had recovered their natural condition and appearance was very remarkable.'

Sir D. Gibb (following Dr. Horace Green) strongly advocates the application of a solution of nitrate of silver (three or four scruples to an ounce of water) in cases of acute laryngitis. The application may be made by means of a full-bellied camel's-hair brush on a curved aluminium wire stem, or by 'the laryngeal fluid pulveriser.' 'The effect of this proceeding is some considerable amount of burning heat, associated with comparatively little spasm, and sometimes dyspnoea, the last two persisting for may be a few seconds only. . . . The relief experienced, and the amelioration in the general symptoms, is observed in periods ranging from half an hour to four hours, and the dyspnoea subsides very speedily.'¹

If, as sometimes happens, the malady advances in spite of all such measures as those above suggested, or if the difficulty of breathing is too urgent to admit of their adoption, tracheotomy must be at once performed. In no class of cases probably is the value of tracheotomy as a life-saving operation more obvious and more pronounced. No definite rule can be laid down as to the period at which it may be desirable to operate. The surgeon must decide in each case when the proper moment has arrived, and must not hesitate to urge in the strongest terms the importance of every minute. There is far greater danger in delaying the operation too long, than in performing it unnecessarily early. The operation itself, if properly performed, is attended by little or no risk.² But it affords immediate relief from the direct suffering. It obviates altogether the recurrence of those frightful paroxysms of dyspnoea, in any one of which the patient may die suffocated. It affords perfect repose to the suffering parts, and saves them from the irritation of the hard-drawn breath. It thus allows opportunity for the subsidence of inflammatory action, and the absorption of effused material. It may not cure, but if performed in time, it certainly ensures a period of safety and freedom from distress, during which the cure may be effected by natural processes. Further, in acute laryngitis the obstruction to respiration is, as a rule, confined to the larynx itself, and the parts below are rarely affected to any serious extent; the malady runs a rapid course, and under favourable circumstances subsides almost as quickly as it arises. Hence, not only is immediate

¹ On Diseases of the Throat and Windpipe, by G. D. Gibb, M.D., 2nd edition, p. 100.

² See an essay by Mr. A. E. Durham, 'On Some of the Difficulties and Dangers of Tracheotomy,' in the *Practitioner*, April 1860.

relief almost absolutely certain, but there is little probability that the cannula need be retained longer than a few days at the outside. While fully impressed with the danger of delay, the surgeon must nevertheless bear in mind that until the patient is actually dead it can never be too late to attempt the operation. And even if it should seem that the last breath has just been drawn, the operation should still be completed, and persevering efforts made to restore life by artificial respiration. Success has crowned such efforts in cases in which the general powers have not been too far exhausted by slow asphyxiation.

Chronic catarrhal laryngitis is sometimes the sequel of one or more attacks of acute or sub-acute inflammation. More often it occurs without being referable to any special cause.

Chronic catarrhal laryngitis is much more frequently met with among adult males than among females or children. This is due in great measure, no doubt, to the more constant exposure to vicissitudes of weather to which men are subject, as well as to the greater demands made upon their respiratory and vocal organs from the nature of their occupations. It often results in cases in which the acute symptoms have not been very severe; or in which they have subsided so far as to permit the patients to resume, without immediate inconvenience, their usual habits before the actual structural lesions have been sufficiently repaired. Hence the necessity for continued rest, watchfulness, and judicious treatment during convalescence from acute catarrhal laryngitis, even though the symptoms may have been comparatively mild. It need scarcely be remarked that when once the chronic affection is established, and so long as it continues, the patient is especially liable to a recurrence of acute attacks, any one of which may be fraught with danger.

The *symptoms* of chronic catarrhal laryngitis are:—hoarseness, want of tone, or some other unnatural condition of the voice; a sense of effort during speaking (especially if at all prolonged), and of fatigue afterwards; frequent desire 'to clear the throat;' and more or less frequent cough, accompanied by occasional but scanty expectoration of thick, greyish, opaque, or semi-purulent mucus. A general sense of discomfort is sometimes experienced, but there is no pain in the part; nor is there any marked tenderness on pressure. Tranquil respiration is, as a rule, performed easily, and without the characteristic whistling or throting sound emitted during inspiration in acute laryngitis. Forced respiration, however, is sometimes accompanied by unnatural sounds, which may be readily heard by means of a stethoscope placed over the larynx or trachea. The cough is no longer 'tearing' and painful, nor harsh, ringing, and 'brassy' as in the acute stages; though often hoarse, and somewhat sonorous, it is not distressing, and suffocative paroxysms very rarely if ever occur. Deglutition is easy and painless.

Thus it would appear that there is nothing absolutely distinctive in the symptoms of chronic catarrhal laryngitis; for very similar symptoms are associated with other totally different conditions to be hereafter discussed. Nevertheless, it is very important that a correct diagnosis should be made, inasmuch as the treatment requisite, as well as the probable issue, may differ very materially from what would be indicated in at any rate some of the other affections alluded to.¹

On *laryngoscopic inspection* the mucous membrane of the larynx is seen to be thickened and unnaturally red, and covered here and there by patches of greyish opaque mucus. The thickening and redness may be either more or less uniform, or irregular and much more pronounced in some parts than in others. In order of frequency the posterior aspect of the epiglottis, the aryteno-epiglottidean folds, the interarytenoid fold, the anterior aspect of the epiglottis, the false vocal cords, and the true vocal cords, are the parts usually affected. In general terms, the acute inflammatory attack is most frequently followed by chronic after-effects in those parts which are naturally most vascular, and most abundantly supplied with glandular structures.

¹ It is also necessary to bear in mind that in some cases the inflammation seems almost entirely confined to the region below the vocal cords. This sub-glottic variety is attended with danger, and is much more difficult to treat successfully.

Ulcers are very rarely seen, but sometimes small superficial cicatrix-like patches may be observed; and occasionally even a dilated blood-vessel or two may be noticed ramifying in the mucous membrane.

The alteration of the voice does not bear any definite relation to the extent to which the true vocal cords are affected. There may be considerable hoarseness, or partial or even complete loss of voice, in cases in which the vocal cords themselves are found on examination to be almost or altogether healthy in appearance. In such cases the explanation may be due either to the swollen condition of the neighbouring parts, which may mechanically prevent the due approximation and tension of the true vocal cords, or may deaden or modify the sound produced by their vibration; or it may be that the surrounding infiltration, or some other effect of the inflammatory process, may hamper or otherwise interfere with the necessary action of the muscles. Whatever may be the explanation in any particular case, laryngoscopy has amply proved (contrary to what was formerly supposed) that the voice may be more or less obviously altered in character, or impaired in power, although the true vocal cords retain their integrity and healthy appearance. The converse is also true. The vocal cords may be visibly affected to some extent in various different ways, as hereafter indicated, without any very serious detriment to the speaking, if not to the singing voice.

The *course and duration* of chronic catarrhal laryngitis vary greatly in different cases. Sometimes it subsides spontaneously in the course of two or three weeks or more. Sometimes, especially if neglected, it remains obstinately persistent; and more or less permanent thickening or hypertrophy (so called) of the mucous membrane results. As a general rule, however, it is amenable to treatment. In some cases of long standing warty growths become developed. In others tracheal, bronchial, or pulmonary complications arise. In all cases there is great liability to fresh attacks of acute or sub-acute inflammation.

Treatment.—The treatment most likely to prove successful in simple catarrhal laryngitis, which has become chronic in character, depends somewhat upon the stage the malady may have reached, and the severity of the symptoms. It rarely happens, however, that any other than local measures are requisite, or indeed beneficial, except in so far as they may tend to the improvement of the general health and strength. But in all cases it is desirable, and in some absolutely necessary, to insist upon the importance of affording to the suffering parts as much rest and as little excitement and irritation as may be practicable. All unnecessary exertions of the vocal and respiratory organs must for a time be avoided. In the subglottic forms of disease tracheotomy may be necessary, but hypertrophy should, if possible, be prevented, by the passage of the hollow vulcanite tubes devised by Schroetter of Vienna. In some cases scarification is found to be of great value.

In the earlier stages of the simple form, the warm soothing vapour inhalations, so beneficial during the period of acute inflammation, must be replaced by more or less frequently repeated applications of astringent solutions, either in the form of spray or by the brush. In a large proportion of cases the inhalation of the spray of weak solutions of alum, tannic acid, or perchloride of iron several times a day—or even of common salt, chloride of ammonium, or chlorate of potash—is all that is necessary. Sometimes, however—and indeed I believe in all cases according to some authorities—it is better to resort at once to the application of a strong solution of nitrate of silver (3j. to 3j. of water) by means of the brush, or sponge probang. Mackenzie recommends a solution of chloride of zinc (30 gr. to the ounce), and in long-standing cases with diminished secretion, half a drachm to a drachm of pure white carbolic acid to an ounce of glycerine.

In the more advanced stages, when the affection has become decidedly chronic in character, and all reasonable hope of spontaneous subsidence, or of improvement under milder treatment, has passed away, the efficiency of the application of the nitrate of silver solution is most marked. The whole surface of the interior of the larynx may be wiped round with the brush; or by aid of the laryngoscope the application may be limited to those parts only which are especially affected. If the sponge

is used, as originally recommended by Dr. Horace Green, precision of application is of course impossible; but the spasmodic contraction excited may serve to squeeze from the sponge a considerable quantity of the solution, which may become diffused over the whole surface. But, as before stated, the brush is far preferable to the sponge. The application is easily made in accordance with the directions already given.

The spasmodic distress, sometimes though not always produced, very speedily subsides. It is well, however, to direct the patient to hold his breath immediately after the application for a few seconds. The good effects are almost immediately perceptible, but are by no means transient. In some cases the application seems to act almost like a charm; and the voice, which before was painfully hoarse, is rendered at once comparatively natural in tone. The application should be repeated once daily, on alternate days, or less often, according to circumstances, until the cure is complete. At intervals between the applications frequent inhalations of the spray of solutions of common salt, chloride of ammonium, or alum may be recommended. Small blisters may sometimes be advantageously applied over the larynx; or counter-irritation may be kept up by means of the strong tincture of iodine, or the iodine liniment.

In cases of very long standing, and especially in those in which the tracheal and bronchial mucous membranes are also affected by chronic catarrhal inflammation, inhalations of balsamic and terebinthinate vapours often prove very beneficial. Turpentine, tar, the balsams of Tolu, Peru, and Canada, or their alcoholic solutions, gum benzoin or benzoic acid, and other similar substances, may be mixed (singly or in combination) with hot water in an appropriate vessel, and the vapour may be inhaled from time to time. Dr. Symonds recommends that substances of this kind should be mixed with æther or pyro-acetic spirit in a wide-mouthed bottle from which the inhalation may be made.¹ Another method consists in keeping the atmosphere of the room in which the patient may be constantly impregnated with the remedial vapours, either by heating portions of the balsamic substances over a spirit-lamp, or by putting them upon hot coals. This method is especially recommended by Trousseau and Pidoux, who state that by its persevering adoption cases of chronic laryngitis have been cured which had not been benefited by interrupted inhalations.² The same authors also refer to the good effects sometimes produced by the empyreumatic oil of burning paper ('l'huile de papier'), and recommend the inhalation of the smoke of cigarettes of paper, either plain or imbued with some arsenical or other medicinal solution.³

Tar water may be inhaled in the form of spray; so also may weak solutions of chloride of zinc, nitrate of silver, &c. But these saline solutions appear to be less efficacious in cases of the class now under discussion than in those which are more recent, and in which the morbid condition of the mucous membrane is less extensive, and less confirmed in character.

Internal remedies sometimes prove useful, especially such as are indicated in catarrhal affections of the respiratory mucous membranes generally, as, for example, decoction of senega with ammonia, the various balsams, chloride of ammonium with tonics, &c.

Men who are subject to catarrhal and other chronic affections of the larynx should wear their beards; and women should be advised to take due precaution for the protection of their necks, especially when they are exposed to cold or vicissitudes of temperature.

¹ The following formulæ are given:—Æther ʒij., benzoic acid ʒiv., Peruvian balsam ʒij.; mix. 2. Pyro-acetic spirit ʒss., æther ʒss., benzoic acid ʒiv., balsam of Peru ʒij.; mix. 3. Æther ʒss., spirits of turpentine ʒss., benzoic acid ʒiv., balsam of Tolu ʒij.; mix. 4. Æther ʒvi., pyro-acetic acid ʒij.; mix. The warmth of the hand is sufficient for volatilising these mixtures.—'Therapeutical Memoranda,' by J. A. Symonds, M.D., *British Medical Journal*, May 1888, p. 448.

CHRONIC GLANDULAR LARYNGITIS. FOLLICULAR DISEASE OF THE LARYNX.
DYSPHONIA CLERICORUM.

Chronic glandular laryngitis is a comparatively common affection.¹ It is most frequently, but by no means solely, met with among those who are subject from time to time to continuous exertion of the voice, as clergymen, barristers, singers, and others. It essentially consists in more or less general enlargement and hypertrophy of the glandules and follicles of the laryngeal mucous membrane, the result of an inflammatory condition which usually commences very insidiously, and always progresses very slowly. It is often, but not invariably, associated with a similar affection of the faucial, naso-pharyngeal, and pharyngeal mucous membranes.

The most frequent cause probably is, as already indicated, continuous exertion of the voice. It is obvious that in prolonged speaking, reading, or singing, the demands made upon the vocal organs are not only greater than during ordinary conversation, but also in some degree different. In ordinary conversation the parts are subject to no great strain; and more or less frequent intervals of rest are afforded, during which the mucous membrane can recover its normal condition. But in the continuous and strong exertion of the voice constantly made by public speakers and singers, the mucous membrane is specially liable to become irritated by the forcible contact, and rapid passage over it, of cold dry air drawn in at each inspiration through the mouth, and not warmed and moistened by passing through the nasal fossæ. To allay the irritation and mitigate the dryness thus produced, the mucous follicles are stimulated to increased activity, and for a time are able to secrete a sufficient quantity of mucus for the lubrication of the surface. Ultimately they are liable to become inflamed and hypertrophied. Further, it is worthy of note that the mucous membrane covering the arytenoid cartilages, and immediately adjoining parts, is more rich in glandular structures than any other portion of the laryngeal mucous membrane. Now this part is constantly subject to a very great extent of motion, and also, perhaps, to considerable strain, during forced vocalisation. And thus its glands are specially liable to be stimulated to increased activity; and the morbid condition under discussion may eventuate.

It is important to bear in mind, however, that chronic glandular laryngitis may, and indeed often does, occur in persons who have not been subject to any such continuous vocal exertions as those above referred to. In such cases exposure to cold and fog (especially if there is any obstruction of the nose), and the constant inspiration of air charged with irritating fumes or particles, appear to be the most frequent causes. Gibb states that he has seen this malady 'in a very exaggerated form in photographers, and in persons much exposed to the fumes of acrid chemicals in confined chambers, and its obstinacy in them is something quite remarkable.'² It is possible also that some constitutional tendency may favour the development of the malady. Indeed, Trousseau, Chomel, De Mussy, and others attribute its origin to the 'herpetic diathesis.'

The symptoms are:—alteration of the voice, and sense of effort in sustaining it—these are by far the most prominent and constant symptoms; more or less discomfort about the larynx, never amounting to pain, but occasionally troublesome; dryness, and sometimes a sense of heat about the throat; and constant desire to clear the throat by 'hemming' and 'hawking.' There is little or no regular cough; and the expectoration which sometimes occurs is slight, scanty, and mixed with saliva. There is neither difficulty in swallowing, nor tenderness upon pressure over the larynx. There are no definite constitutional symptoms: but the general health and spirits of the patient are often observed to be more or less depressed.

¹ This affection appears to have been accurately and fully described by Dr. Horace Green of New York, to whom also is due the credit of having especially taught and insisted upon the proper method of treating this and other affections of the larynx by the topical application of solutions of nitrate of silver, &c. See *A Treatise on Diseases of the Air-Passages*, by Horace Green, M.D. New York. 1848.

² *On Diseases of the Throat*, op. cit. p. 2.

The alteration in the voice depends upon the swollen condition of the arytenoid mucous membrane, which prevents the free movement of the cartilages, and thereby the necessary approximation of the vocal cords. The character of the voice varies somewhat. In the earlier stages it is simply wanting in clearness and tone and general reliability. In the later stages it becomes disagreeably harsh, husky, and hoarse. Sometimes it fails altogether, and the patient speaks in a husky whisper. As a general rule, the alteration in the voice is most pronounced in the early morning, before the vocal organs have been at all exercised, and again in the evening, or after any considerable exertion of the voice, when the parts have become fatigued. Sometimes the patient will feel that he is able to carry on ordinary conversation with ease; but directly he begins to read or speak continuously in a loud voice, he finds it impossible to proceed; or he only does so with great difficulty, sense of effort, and subsequent fatigue.

On inspection, the mucous membrane of the fauces and back of the throat is usually seen to present a more or less raw and irregularly granulated appearance; and the enlarged glandules, each (it may be) surrounded by a little halo of undue redness, may be recognised studding the surface. *Laryngoscopic examination* shows that the mucous membrane of the larynx is similarly affected; and in some cases, as already indicated, the malady is confined to the larynx. The parts most frequently and most obviously affected are, as might be expected, those in which the glandules are most abundant. These parts are the mucous membrane covering the arytenoid cartilages, the inter-arytenoid folds, the base of the epiglottis, and the ventricles and sacculi of the larynx. In cases of long standing, points of ulceration may sometimes be observed, especially about the base of the epiglottis. In others, the glandules appear to be not simply enlarged, but distended with opaque yellowish material.

The mucous membrane covering the vocal cords is very thin, and contains very few if any glandules. It is very rarely, therefore, observed to be affected in this malady. It occasionally presents, however, isolated granulations which might possibly be mistaken for enlarged glandules. Such a condition is described by Türk under the name of *Chorditis tuberosa*.¹

The course of chronic glandular laryngitis is very tedious, and its duration very long, often extending over months or even years. It is not readily amenable to treatment, but by perseverance much good may generally be effected. Certain forms of new growth occasionally met with in the larynx may not improbably owe their origin to the localisation of this or some allied affection of the mucous glandules.

Treatment.—The method of treatment, which experience has shown to be the most effectual, consists in the application by the brush of solutions of nitrate of silver, or perchloride of iron, at intervals varied in frequency according to circumstances. The nitrate of silver, I believe, is, as a rule, the best application. Sulphate of zinc, sulphate of copper, and tincture of iodine² have also been recommended, and indeed it may be stated that it is often well to vary the application. That which answers perfectly in one case, or at one period, proves less efficacious in others, or at other periods, and under changed conditions in the course of the same case. Any points of ulceration that may be seen should be touched by means of the probe with solid nitrate of silver. Between such applications spray should be inhaled at frequent intervals during the day. The best solutions for the purpose are those of common salt, chloride of ammonium, iodide of potassium, and in some cases alum, or weak solutions of perchloride of iron. Certain mineral waters, especially such as contain the sulphides of sodium or calcium, have also been strongly recommended, as well as artificial solutions of sulphurous acid.

A method of treatment, which appears to be especially useful in this form of laryngeal disease, consists in slowly sucking mediated lozenges. The precise and careful observations of Fournié³ prove (contrary, perhaps, to what might be expected) that certain portions of liquid swallowed, especially if swallowed slowly, or allowed

¹ See *op. cit.* p. 164.

² Iodine, 1 part; iodide of potassium, 3 parts; distilled water, 18 parts. (Krishaber.)

³ *Etude pratique sur le Laryngoscope et sur l'application des remèdes topiques dans les voies*

almost insensibly to find their way down the pharynx, may become applied to the upper part of the larynx, and even diffuse themselves to some extent over its internal surface. The lozenges that appear to prove most useful are those containing chloride of ammonium, with or without cayenne, and the 'red-gum lozenges' made by Messrs. Squire.

In this, as in other chronic laryngeal affections, the beard should be worn; and all due general precautions should be taken: for, as need scarcely be stated, an attack of ordinary catarrhal laryngitis may be readily excited.

Tonics and other constitutional remedies, varied according to circumstances, often prove very beneficial. It is especially necessary to reassure the mind of the patient; for he is but too often depressed in spirits, and apt to think his malady far more serious than it really is.

PHTHISICAL LARYNGITIS. TUBERCULOUS LARYNGITIS. THROAT CONSUMPTION.

The larynx is found to be more or less seriously affected in a very large proportion of cases of tubercular phthisis.¹ In some rare cases, the earliest recognisable indications of the commencement of the malady appear in the larynx. It is usually, however, a secondary manifestation, is rarely developed before puberty, being common in adults between the ages of twenty and thirty, affecting men more than women. In many cases, when the malady is fully established, the laryngeal symptoms are the chief if not the only source of the distress from which the patient suffers. In others, again, the condition of the larynx gives rise to effects which may to a considerable extent mask or simulate the physical signs and symptoms of incipient, and even of advanced, pulmonary disease; and thus the diagnosis may be rendered very difficult.² Hence the importance of making careful laryngoscopic examinations in all cases of suspected phthisis, and especially in such as present indications of laryngeal mischief.³ There can be no doubt, I think, that most of the so-called 'cures of consumption' said to have been effected by local applications and inhalations (in so far as the accounts given may be considered reliable) have occurred in cases in which the larynx has been principally, if not solely, affected.

In the very earliest stages, the *symptoms* of phthisical laryngitis are simply weakness, uncertainty, slight huskiness, and occasional failure of the voice, together with a more or less constant desire to clear the throat of the thick whitish mucus which accumulates from time to time. On *laryngoscopic examination*, the mucous membrane is seen to present a peculiar dotted granular appearance, which is usually first, and as a rule most conspicuously, manifest on the posterior aspect of the epiglottis. This appearance is probably associated with the earliest deposit of tubercular material taking place in minute quantities at many distinct points. Somewhat later, the mucous membrane covering the arytenoid cartilages, and the aryteno-epiglottidean and interarytenoidean folds are affected, and sometimes present granulation-like elevations. At the same time, more or less thickening of the mucous membrane may be observed, and this is most commonly at first confined to the outer surfaces of the arytenoid cartilages, which appear as tumid pyriform swellings. The thickening is an important and almost characteristic feature. It is to some extent due to

respiratoires. Par le docteur Edouard Fournié. Paris, 1863. Also *L'Union médicale*, 5 fév. 1863, p. 248.

¹ Louis states that he found ulceration of the larynx in 63 out of 193 cases of phthisis which he examined. *Researches on Phthisis*. By P. C. A. Louis, M.D. *Sydenham Soc. Trans.* Lond 1844. According to the records of post-mortem examinations made at Guy's Hospital during six years, it appears that the larynx was affected in 47 out of 145 cases. The epiglottis is considered as part of the larynx; some cases, therefore, are included in these numbers in which the epiglottis only was affected.

² Cases occur from time to time in which affections of the larynx and trachea so closely simulate pulmonary disease that the patients are falsely supposed to be in a state of 'hopeless consumption.' On this subject see especially Dr. Scott Alison *On Morbid Conditions of the Throat in their Relation to Pulmonary Consumption*, p. 10 *et seq.* London, 1860.

³ See the excellent remarks of Dr. Marcet on the value of the laryngoscope in the diagnosis of phthisis, in his *Work On Diseases of the Larynx*, *op. cit.* p. 80 *et seq.*

increased deposit of tubercular material as well as to inflammatory infiltration. The false and true vocal cords, as a rule, become implicated only at a still later period, and usually on one side first. The false vocal cords partake of the general thickening, and often hide the true vocal cords; and these latter lose their clearness and brilliancy. In many cases, the first evidence of the disease is a peculiar pallor of the mucous membrane, not only of the larynx, but also of the mouth, palate, and pharynx, due to impaired nutrition. As the malady advances, ulceration occurs in one part or other, and usually first on the posterior aspect and lower part of the epiglottis. At or about this period, the voice becomes hoarse; breathing is carried on with a sense of effort, and sometimes with difficulty and pain; the cough (before rare, and indeed often little more than a more or less frequent 'hemming') becomes constant, and sometimes painful; the expectoration is increased in quantity, and somewhat changed in character, becoming yellowish and occasionally slightly streaked with blood; and sometimes, according to the position of the ulceration, there is pain in swallowing. So long as the ulceration is confined to the posterior surface of the epiglottis, swallowing is easy; but when the edges, upper border, and anterior surface of the epiglottis, and especially the glosso-epiglottidean folds, are implicated, swallowing becomes painful. The ulcerative process, after it has once commenced, goes on—slowly, it may be, but surely nevertheless. It extends gradually, not only superficially, but also in depth. Fresh centres of ulceration often appear; and by-and-by the deeper structures, areolar tissue, cartilages, &c., become involved, and in turn destroyed. Inflammatory swelling and œdema of the surrounding parts supervene. When the perichondrium is attacked, the subjacent cartilage may either share in the ulceration and become gradually eaten away, as frequently happens to a greater or less extent with the epiglottis; or it may become partially or wholly necrotic, and may give rise to the formation of an abscess, in the midst of which the necrosed portions may remain for a longer or shorter period. The arytenoid cartilages appear to be most frequently and earliest liable to become necrotic; next the cricoid cartilage. The thyroid is comparatively rarely affected in this way. It would seem that before becoming necrosed the cartilage generally undergoes a process of calcification. Concomitantly with these morbid changes, the expectoration becomes abundant and purulent; the voice is lost; breathing becomes more constantly difficult and painful; and from time to time the most distressing paroxysms of spasmodic dyspœa may come on. Under such circumstances, laryngoscopic examination is often very difficult, not only on account of the general state of the patient, and the hyperæsthetic condition of the pharynx commonly existing in such cases, but also on account of the malposition, deformity, and swelling of the epiglottis resulting from the disease, and the abundant mucopurulent secretion by which the view is often completely obscured. When, however, a view is obtained, some idea may be formed as to the character and extent of the ulceration and destruction of parts that may have taken place. And it will usually be observed that the epiglottis and the posterior and upper parts of the larynx have suffered to the greatest extent; and that the ulcers are surrounded by more or less considerable thickening of the surrounding parts. Sometimes even projecting points of necrosed cartilage may be seen exposed, or bathed in pus. Post-mortem examination (the opportunity for which, as a rule, speedily occurs) confirms the correctness of such observations, as well as the inferences drawn from them.

In some cases the ulcerative process does not commence so early, nor extend so deeply, as thus stated; and it may even happen that healing may take place. In certain exceptional cases under favourable circumstances the process of healing may be watched from time to time by aid of the laryngoscope, as I know from my own observation, as well as from the statements of others. And further, it is by no means very unusual to find on post-mortem examination the cicatrices of healed

FIG. 151. — Laryngeal Phthisis, showing pyriform swelling of the ary-epiglottic folds. (MacKenzie.)

ulcers in the larynges of those who have died of phthisis. In other cases thickening followed by softening, and it may be by subsequent absorption, without definite ulceration, may be observed to take place in localised patches. During this process there is abundant expectoration of thick whitish mucus. In all such cases the symptoms are proportionately less severe and the progress of the malady is much slower than in cases of the class first described. Post-mortem examination not unfrequently shows more or less pronounced affection of the larynx in cases in which during life there have been scarcely any laryngeal symptoms beyond slight hoarseness, or some other alteration of the voice.

The *course and duration* of phthisical laryngitis vary greatly, not only with the special character and type of the local affection, but also still more notably with the degree of development and severity attained by the pulmonary disease, and the general morbid condition at the period at which the larynx first begins to suffer. Thus, in the first place, as already stated, the disease may in certain rare cases begin in the larynx, and there may be no indications whatever of the presence of tubercle in any other part. In the second place, the larynx may appear to become affected almost simultaneously with the lungs, and the disease in the two parts may go on almost *pari passu*. In the third place, the affection of the larynx may be consecutive to advanced disease and disorganisation of the lungs, and may even supervene, as it were, almost at the very termination of the case.

In cases belonging to the first class indicated, the progress may be comparatively rapid, and the patient may die asphyxiated from the results of the laryngeal disease alone; or exhaustion may come on gradually. More frequently, however, the progress of the malady is slow; and sometimes apparent or even actual recovery of temporary character may take place. But sooner or later the malady appears afresh, often with greatly increased severity; and all the signs and symptoms of pulmonary mischief become manifest.

In cases belonging to the second and third classes indicated, the downward progress is almost invariably more or less rapid. It too often happens that the patient seems prematurely hurried to his end by the difficulty of breathing and swallowing, and all the various sources of distress associated with the laryngeal complications of his fatal but otherwise almost painless malady.

It may be broadly stated, however, that patients afflicted with this malady rarely survive longer than two years, the largest proportion dying between the twelfth and the eighteenth month after the first onset of the laryngeal mischief.

Treatment.—It would be altogether out of place to discuss in these pages the constitutional treatment requisite in tubercular affections generally, and in pulmonary phthisis especially. Suffice it to say, that similar constitutional treatment is indicated in phthisical laryngitis. It must ever be borne in mind that this malady is but a local expression, so to speak, of a general morbid tendency, to modify which all possible endeavours must be made. At the same time, the part affected is so important, and the associated danger and suffering may be so great, that no measures must be neglected by means of which the symptoms may be alleviated and the danger averted, if only for a time. Experience amply shows that in such respect local treatment is often very beneficial.

In the earliest stages it does not appear that any typical applications are likely to be efficacious in arresting the malady; but rest to the parts affected, and avoidance of all sources of irritation, may afford opportunity for general improvement under constitutional treatment. But when once ulceration has commenced the need for local treatment arises, and indeed may become most urgent. Soothing inhalations of the steam from hot water in which hemlock, hops, stramonium, or opium have been infused, often afford much comfort. So also do spray inhalations of anodyne solutions. Similar solutions applied by the brush are sometimes very useful. They may not cure, but they give the temporary relief the sufferer so often and so anxiously looks for. An excellent formula quoted from Krishaber¹ is as follows: Extract of opium and extract of belladonna equal parts, dissolved in forty parts of cherry-laurel

¹ *Op. cit.* p. 674.

water. The beneficial effects of this application, although transient, are immediate and almost invariable. The insufflation of $\frac{1}{2}$ of a grain of morphia, once or twice daily, often greatly alleviates the cough. This should be mixed with a couple of grains of starch.

Small ulcers may often be advantageously touched with the solid nitrate of silver: a protective covering from the irritating influence of the passing breath is thus formed for them. But the application of the solution of nitrate of silver to the mucous membrane generally appears in many cases to do harm rather than good. Marret recommends repeated scarification of the thickened parts of the mucous membrane.¹

In cases in which the dyspnoea is great, and clearly dependent upon the condition of the larynx—in cases especially in which there is great difficulty in swallowing, and consequent danger of death from want of sufficient nourishment—tracheotomy should be performed without hesitation.² The existence of even extensive disease in the lungs cannot be regarded as forbidding the adoption of this certain mode of relief from those symptoms which alone are distressing. Death from pulmonary phthisis is always easy; but death from laryngeal phthisis is preceded and attended by the direct suffering. Tracheotomy cannot ward off the one mode of death; but it is powerful to rob the other of its horrors. I have seen such immediate and such complete relief afforded by the operation in several cases, about the hopeless character of which there could be no doubt, that I should never hesitate to repeat it in similar cases, feeling certain that though life may not be saved, it may be prolonged, and suffering may assuredly be diminished during the remaining days. Further, it may be added that cases do occur from time to time in which the whole disease is in the larynx, although the accompanying symptoms and wasting closely resemble those of general phthisis, and the physical signs are so far obscured as to afford no reliable indications. Three cases have come under my observation, in each of which the patient had been pronounced to be dying of 'hopeless consumption.' In each of these, more or less complete recovery speedily followed the performance of tracheotomy.

SYPHILITIC LARYNGITIS.

Syphilitic affections of the larynx are comparatively common.³ They vary in character and importance with the period of the disease at which they arise, and also with the general health and condition of the patient.

During the *Secondary Stages* of Syphilis the mucous membrane of the larynx may be affected in a manner corresponding with the cutaneous eruption present; or it may become ulcerated, either independently, or in direct continuity with the characteristic ulceration of the soft palate, fauces, and pharynx, which so commonly occurs. The actual existence of the several conditions referred to has been fully established in very many cases, and may as a rule be readily recognised, by aid of the laryngoscope.⁴ Without such aid the precise condition of the larynx in any particular case can only be inferred from the symptoms; and a considerable degree of uncertainty necessarily attends the diagnosis.⁵

Erythema of the laryngeal mucous membrane often occurs in association with

¹ *Op. cit.* p. 95.

² It is very desirable, in every case where swallowing is difficult, to thicken the food of the patient by adding to it corn-flour or arrowroot.

³ According to my own experience a very large proportion (from thirty to forty per cent.) of the cases of laryngeal disease met with in hospital practice, among the surgical out-patients, are of syphilitic origin. In private practice the proportion is very much smaller, but still considerable.

⁴ On this subject, see especially the brochure of M. Dance, *Sur les éruptions du Larynx dans la période secondaire de la Syphilis*. Paris, 1864.

⁵ Gerhard and Roth state that in eight out of fifty-four cases of secondary syphilis under observation in Würzburg Hospital, the hoarseness was produced by mucous patches or condylomata of the larynx, which could be distinctly seen by aid of the laryngoscope. *Arch. f. path. Anat.* Bd. xxi. Heft 1.

syphilitic roseola of the skin. It may either extend from the fauces to the épiglottis and upper part of the larynx, and thence spread over the whole mucous surface; or it may appear in isolated and more or less well-defined patches. The mucous membrane in the parts affected presents on laryngoscopic inspection a dusky red or even purplish hue, and, it may be, a slightly elevated or swollen appearance.

More distinctly elevated and better defined patches (*mucous patches*) are sometimes seen in association with papular, squamous, and especially with tubercular affections of the skin.

The *symptoms* accompanying these comparatively simple conditions are not, as a rule, severe; nor are the results likely to prove serious. The voice is generally altered to some extent; it may become weak, wanting in tone, husky, or somewhat hoarse. But there is neither dyspnoea nor troublesome cough; nor is there local pain, nor any difficulty in swallowing that can be referred to the affection of the larynx.

The peculiar character of the voice so constantly noticed in secondary syphilis, and by some considered almost pathognomonic, would appear to depend in great measure upon one or other of the conditions of the larynx thus described, rather than upon the concomitant affection of the palate, fauces, and nasopharyngeal mucous membrane, the existence of which is more readily obvious, and to which alone the explanation is commonly attributed. Such, at any rate, is the conclusion indicated by the results of my own observations, as well as by those of others. It must be borne in mind that an affection of the mucous membrane of the larynx which is only superficial, and to the eye of the observer appears slight, may nevertheless, directly or indirectly, hamper to a considerable extent the movements necessary for the production of the natural voice.

It sometimes happens that laryngeal symptoms, similar in character to those just described, and associated with similar laryngoscopic appearances, arise either gradually, or almost suddenly, five or six months after the commencement of the malady, and after all obvious affections of the fauces and pharynx have subsided.

Syphilitic ulceration, as already stated, may extend from the fauces and pharynx to the larynx. But it very rarely does so during the secondary stages, except in cases in which the general health and strength are much broken down, or in which there has been continuous or frequent exposure, during the course of the malady, to the ordinary causes of acute laryngitis.

Occasionally small isolated spots of superficial ulceration, similar to those often observed in the mouth, appear on the laryngeal mucous membrane.

During the *tertiary stages* of syphilis the larynx is frequently affected in one way or other, and in many cases to a very serious extent.

Papulo-tubercular elevations of the mucous membrane are by no means rare. They vary in size, and also in situation. In some instances they simulate warty growths of more innocent origin; in others they more or less closely resemble the condylomata met with on other mucous surfaces.¹ Sometimes these elevations subside under appropriate treatment, or perhaps spontaneously. In rare instances they increase to such size as to necessitate removal by operation. Sometimes they ulcerate and form the starting-points of ulcerations, such as are described in the next paragraph. They have been observed on the false and on the true vocal cords, as well as on various other parts of the laryngeal mucous membrane. The chief *symptoms* noticed are hoarseness, or some other marked alteration of the voice, and sometimes occasional fits of dyspnoea.

Tertiary ulcerations of the larynx are comparatively common. They may commence either superficially in the mucous membrane, and thence penetrate to the subjacent structures; or they may result from the effects of some more deeply seated affection—as, for example, softening down of gummatous deposit in the submucous

¹ M. Cusco has especially called attention to growths of this description, and to their syphilitic origin (see M. Dance, *op. cit.*) His observations accord with those of Türk and other observers, and are confirmed by my own experience.

tissue, or perichondritis or chondritis—followed by the formation of abscess. They may occur singly, and in any part; usually, however, several spots are attacked, either simultaneously or one after another. The epiglottis is generally affected first, and in a large proportion of cases is the part most extensively destroyed. Sometimes its edges are gradually eaten away; sometimes its substance early becomes perforated, and the perforation extends until the edges are reached. In such cases semi-detached portions, flapping loosely, occasionally give rise to much embarrassment. The false and true vocal cords are often affected—in some cases by comparatively superficial, but in most by deeply penetrating, ulceration. The mucous membrane covering the arytenoid cartilages, and the posterior part of the larynx generally, is comparatively less frequently and less early attacked by syphilitic than by phthisical ulceration: but it is liable to become involved sooner or later. The cartilages (and especially the arytenoids) may become carious or necrotic, as the result either of deep extension of ulceration commencing in the mucous membrane, or of perichondritis arising independently of any such superficial affection. Portions of dead cartilage may become detached, and, acting as foreign bodies, may give rise to the most serious symptoms; or they may be expectorated, or removed by operation; or they may remain at any rate partially fixed, and in such case may become the foci of abscesses, and the excitants from time to time of the most dangerous paroxysms of spasmodic dyspnoea.

The *symptoms* vary according to the extent of the ulceration and the part especially affected. There is invariably marked alteration of the voice, sometimes hoarseness, sometimes complete aphonia, and sometimes one or other of the various intermediate conditions which are readily recognisable but difficult to describe or name. There may or may not be dyspnoea; and the dyspnoea, if present, may be slight, or of the most distressing character. In some instances, and especially in those in which the cartilages are affected, there may be occasional attacks of severe dyspnoea, with intervening periods of comparative or even complete ease; and sometimes suffocative spasm of the larynx may occur.

Two or three years ago, a patient (in the Venereal Ward in Guy's Hospital), who had suffered from occasional and slight but evanescent attacks of dyspnoea, was suddenly seized with such urgent and distressing difficulty of breathing, that he rushed from the ward to seek help. He reached the bottom of the stairs, and there fell dead from suffocation. On post-mortem examination, a detached portion of necrosed cartilage was found in the glottis.

It is well to bear in mind, therefore, that in such cases dyspnoea of the most dangerous character may supervene suddenly, and almost without warning. Indeed, it may be asserted that patients suffering from severe tertiary affections of the larynx require the most careful watching, for danger may arise at any moment. In some cases there is difficulty in swallowing; and often more difficulty in swallowing fluids than solids. The former (on account of the condition of the epiglottis) are more liable than the latter to 'go down the wrong way.' But the slight degree of difficulty, and the absence of all pain in swallowing, sometimes observed in certain exceptional cases of this kind, in which the epiglottis has been even extensively destroyed, are very remarkable.

The *course and duration* of these tertiary affections of the larynx, as may be readily understood, vary greatly. In some cases, under appropriate treatment, cicatrization may take place; but in such it constantly happens that very serious deformities of the parts result either from the loss of substance, or from the subsequent contraction of the cicatrices that may have occurred. The voice is, as a rule, permanently impaired; and breathing and swallowing may be rendered more or less difficult. Attacks of acute laryngitis, attended by more or less spasm, are liable to be excited by comparatively slight causes, and may lead to a fatal result if timely relief is not afforded, or if the safety of the patient has not been previously secured by the performance of tracheotomy.

The *general diagnosis* of syphilitic affections of the larynx is not often difficult. The history of the case, and the presence of the syphilitic cachexia, together with the coexistence of some more unmistakable signs or symptoms (such as ulcers or cicatrices

about the palate and fauces, cutaneous eruptions, nodes on the tibiae, &c.) generally serve to indicate the nature of the malady.

But beyond the general indications afforded by the history of the case, and by the presence or absence of other local affections of syphilitic origin, certain special indications may be obtained, and the diagnosis may often be clearly established, by aid of the laryngoscope.

The dusky hue and patchy appearance of syphilitic erythema of the larynx differ notably from the bright diffused redness of simple catarrhal inflammation; and the papules, flattened tubercular elevations of surface, and condylomata of syphilis can hardly be mistaken for the enlarged mucous follicles of glandular laryngitis—still less for the dotted, granular appearances presented in the earlier stages of laryngeal phthisis. There may, however, be considerable difficulty in distinguishing between a syphilitic tubercle or condyloma beginning to ulcerate, and a small epithelioma, especially if situated on the posterior wall of the larynx. Such difficulty has arisen in more than one instance under my observation. In any doubtful case it is well to try the experiment of 'specific' treatment before expressing any decided opinion. Antisyphilitic remedies and local treatment will almost certainly effect a cure in the one case; and in the other, though necessarily useless, they cannot do any great amount of harm.

The deep and extensive ulceration of the more advanced stages of syphilitic disease of the larynx not only gives rise to symptoms, but on laryngoscopical inspection may present appearances which more or less closely resemble those of phthisical disease on the one hand, and epithelioma on the other. It may not be easy, but it is always important, to determine accurately the nature of the malady, as well as the extent of the mischief. For, as need scarcely be stated, the treatment which is requisite and likely to prove more or less successful in cases of syphilitic origin, might be absolutely injurious in those associated with phthisis, and altogether useless, or perhaps worse than useless, in epitheliomatous disease. The prognosis also must obviously depend in great measure upon the satisfactory determination of the origin of the local affection.

The chief distinctive features presented by syphilitic, phthisical, and epitheliomatous ulceration of the larynx may be stated as follows.

Syphilitic ulceration usually attacks the epiglottis first, and most frequently its upper surface. It extends rapidly, perhaps in the course of a few days, and is emphatically destructive in its progress. It involves the submucous tissues at a comparatively early period; and thus the whole thickness of the epiglottis may speedily become perforated, or some other part of the larynx may suffer corresponding destruction of substance. It is not, as a rule, surrounded by any marked or extensive thickening; but its edges are often more or less swollen, and red. Such apparent or real thickening as there may be generally attends rather than precedes the ulcerative process.¹ The accompanying expectoration is thick, tenacious, and yellow, or yellowish green in colour.

Phthisical ulceration usually commences in the mucous membrane covering the upper and anterior parts of the arytenoid cartilages. The posterior aspect of the epiglottis may often be seen at the same time free from ulceration, but presenting the dotted granular appearance already described. It is almost invariably preceded as well as always attended by marked and characteristic thickening. It progresses very slowly; and, as a rule, does not penetrate at an early period to the deeper structures. When it attacks the epiglottis, the edges present an irregular, somewhat worm-eaten and greyish appearance, but the under surface is usually first attacked. The ulcers are smaller, and almost always numerous. The accompanying expectoration is generally more frothy, and thinner, and more mucopurulent in character than in syphilitic ulceration, and much more abundant than in epithelioma.

Epitheliomatous ulceration of the larynx in a very large proportion of cases commences on the pharyngeal aspect of the mucous membrane covering the arytenoid or

¹ The ulcers thus formed are deep and most often solitary.

cricoid cartilages, and comparatively rarely in the interior of the larynx. It is associated with very considerable and irregular thickening, due to the development and increase of the new growth. Its surface presents a dirty greyish appearance, and its edges are elevated. It progresses slowly. The accompanying expectoration, at any rate during the earlier stages, is scanty, thin, and often more or less sanious in character. In the advanced stages it becomes abundant, more or less purulent, and sometimes tinged with blood.

The other local and constitutional signs and symptoms, which in syphilitic and phthisical cases may aid the diagnosis, are altogether wanting in cases in which the laryngeal ulceration is simply epitheliomatous in origin.

Lupous and other Strumous ulcerations of the larynx which cannot, strictly speaking, be classed as phthisical, sometimes occur,¹ and are with difficulty distinguished from those of syphilitic origin. In some cases of the kind that have come under my observation, it has seemed that the affection has probably been due to congenital syphilis. The age of the patient, the history of the case, and the presence or absence of other local or general indications, afford the best guides in the diagnosis.

Treatment. In syphilitic laryngitis, local as well as constitutional treatment is very often necessary, and in the more severe forms is urgently—nay, imperatively demanded.

The comparatively slight affections which so commonly occur during the secondary stages of the malady, and in which there is simply diffused or patchy erythema of the mucous membrane with but little swelling, as a rule, subside under constitutional treatment. But all unnecessary exertion of the voice, and especially exposure to cold and wet, should be sedulously avoided. Mercury in one form or other is the only remedy upon which any reliance can be placed; and the appearance of laryngeal symptoms may generally be accepted as an indication that it is desirable to get the system under the influence of this drug as speedily as may be practicable and safe. The use of the calomel vapour bath may be especially recommended in such cases, inasmuch as beyond its general efficiency it affords special facility for the occasional inhalation, and thereby the local application, of the mercurial vapour. The value of such inhalation, however, is more pronounced in cases in which ulceration has commenced.

Secondary ulcerations of the laryngeal mucous membrane (whether in continuity with others about the fauces or pharynx, or appearing independently) may often be advantageously treated by local applications. But such applications must be regarded simply as adjuvants to the general treatment indicated, and not as in any measure rendering such general treatment unnecessary. The frequent inhalation of the spray of weak solutions of perchloride of mercury with chloride of ammonium, or of sulphate of copper, very often appears to be beneficial. In some cases the insufflation of calomel, or an occasional inhalation of the vapour of calomel, may be recommended. In other cases the application of solid nitrate of silver or sulphate of copper, from time to time, to the ulcerated surface does good. If there is much irritability, however, the inhalation of warm soothing vapours, or the spray of anodyne solutions, is for a time preferable.

Syphilitic affections of the larynx occurring during the tertiary stages of the malady almost invariably require the administration of iodide of potassium in full doses (gr. xx. to gr. xxx.) three or four times a day. In some cases the addition of iodine may be useful. In others, iodide of iron and tonics generally are indicated. Local measures are very often necessary in conjunction with the constitutional treatment indicated, and in all cases may do much to aid the cure. Condylomatous and papillary elevations of the surface may be touched daily, or less frequently, with the solid nitrate of silver. In cases in which ulceration has occurred, inhalations of the vapour of iodine, or of the spray of solutions of iodide of potassium, and iodine are very useful. If the ulcers are comparatively superficial, the application of solid sulphate of copper daily, or twice daily, often proves beneficial. If the ulcerated surface is extensive, a saturated solution of sul-

¹ See Türck, *op. cit.* p. 425.

phate of copper may be advantageously applied by the brush. Cases occasionally occur in which the internal administration and also the local application of mercurials in conjunction with preparations of iodine are indicated. The more powerful applications and medicines may sometimes be beneficially alternated from time to time with the exhibition of chlorate of potash, both locally in the form of solutions, spray, or powder, and internally in combination with tonics. Swollen and edematous parts of the mucous membrane may be freely scarified with the greatest advantage; and any spot at which an abscess appears to have formed may be punctured. If any portion of exposed and necrosed cartilage should be seen, an attempt may be made to remove it by means of appropriate forceps.

In every case in which breathing becomes seriously impeded, whether in the secondary or tertiary stages of the malady, tracheotomy should be performed without hesitation. Ample experience proves that in syphilitic disease of the larynx this operation may be regarded as fairly successful, not only in averting impending danger, but also in affording opportunity for the more or less complete restoration of the parts affected.¹ The operation is especially called for in cases in which paroxysms of spasmodic dyspnoea have occurred, or in which laryngoscopic examination shows that the ulceration is extensive and deep, and some portion or other of necrotic or carious cartilage is exposed. In such cases recovery without operation, though by no means impossible,² is at any rate improbable; and the patient is in peril of his life (peril which at any moment may become imminent) until a new way of breathing is secured to him.

The cicatrices of syphilitic ulcers of the larynx have a great disposition to contract, and such disposition is favoured in many cases by the loss of substance which may have occurred. Permanent impairment of the voice, and more or less serious impediment to respiration, may result. It not unfrequently happens that tracheotomy becomes necessary after partial or complete cicatrization has taken place, in consequence either of the resulting contraction of the parts, or of an attack of laryngitis incidentally occurring. The damaged parts are prone to a low sub-acute or chronic form of inflammation, which at any moment may become exacerbated and give rise to urgent symptoms. In some cases the passage gradually becomes more and more free in consequence of the absorption of effused material; and in such, if it should have been necessary to perform tracheotomy, the cannula may be removed at an earlier or later period. In other cases the contraction increases, and the tracheotomy cannula must be worn during the remainder of life. In some few cases it may seem desirable to divide the cicatrices by operation, and to attempt the dilatation of the air-passage. But so far as I have been able to ascertain, no very satisfactory result has hitherto been obtained in any case in which the mischief has been in the larynx itself. Much good, however, has been effected in several cases in which the contractions have been situated above the larynx. Some encouragement to further attempts may perhaps be derived from the successful results which have been obtained in instances in which the contractions have resulted from the effects of injuries, although, as is obvious, the conditions in such cases must necessarily be somewhat different.³ Dr. Mackenzie speaks highly of Dr. Whistler's 'cutting dilator' in those cases in which a web has formed in the larynx. Professor Schroetter's dilator, in cases in which tracheotomy has been first performed, may occasionally be used with advantage.

¹ In 38 out of 72 cases of tracheotomy on account of syphilitic disease of the larynx which have come under Mr. Durham's observation, or of which he collected particulars, life was preserved. In 19 of these the patients were enabled sooner or later to dispense with the cannula; in 10 it was necessary to wear the cannula permanently; in 9 the ultimate results are not stated.

² See a remarkable case recorded by Gibb (*op. cit.* p. 38) in which a crater-like elevation was seen on one side of the glottis. From this, portions of the cricoid cartilage were discharged and expectorated on three different occasions.

³ See the article on INJURIES OF THE NECK.

ERYSIPELATOUS LARYNGITIS.

Erysipelatous laryngitis in its severer forms is an extremely dangerous but happily by no means a common affection. It is most frequently met with, perhaps, in hospital practice at periods when erysipelas is prevalent. It may either occur in association with erysipelas of the face and neck by direct extension to the fauces, and thence to the larynx; or the fauces and larynx may be first affected, and death may ensue without any appearance of erysipelatous redness on the external surface.

The *local symptoms* are:—soreness of the throat; difficulty in swallowing; pain and tenderness about the larynx; hoarseness, and subsequently extinction of the voice; and difficulty in breathing, which may rapidly become more and more urgent. These local symptoms are preceded and attended by the constitutional symptoms (such as feverishness, rigors, &c.) associated with erysipelas generally. On *inspection*, the mucous membrane of the fauces is seen to be unnaturally red and swollen, and sometimes more or less dry and shining. By aid of the laryngoscope, the mucous membrane of the larynx may be seen to be similarly affected. As the malady advances the submucous tissue becomes infiltrated; the swelling increases, and its oedematous character is pronounced; the glottis becomes more and more encroached upon, and respiration is consequently more and more impeded.

Unless the malady is checked in its progress, or relief is afforded from the urgent symptoms, the patient usually sinks into a 'typhoid' state, and dies either from exhaustion or suffocation. Such is the common result.

On *post mortem examination* the mucous membrane of the larynx appears inflamed, swollen, and oedematous. In many instances it is of a dirty greenish colour in places; and the submucous tissue is infiltrated with seropurulent matter, and here and there sloughy. Small collections of pus and sloughs of the areolar tissue are occasionally seen round the glottis. The tracheal mucous membrane is also often found to be inflamed. The mucous membrane of the fauces is similarly affected; and the base of the tongue and the tonsils sometimes present a more or less extensive sloughy appearance.

Treatment.—The general treatment must be from the first stimulating and supporting; and no effort must be spared to counteract the depressing influences of the disease. As much nourishing and easily digestible food as can be taken, together with a very liberal allowance of wine or brandy, should be given at frequent intervals in such proportions as can be swallowed. The tincture of the perchloride of iron with quinine should be administered in full doses, or some other powerful tonic combined with chlorate of potash, or ammonia.

In some cases it may be desirable to commence the treatment by the administration of an emetic followed by a purge. But the propriety of so doing must be decided by the general condition of the patient, and the progress the malady may have made. Locally, the application of a strong solution of nitrate of silver or perchloride of iron may be recommended in the earlier stages. The insufflation of morphia ($\frac{1}{4}$ gr.) mixed with starch twice or thrice daily, the patient at the same time constantly sucking ice, together with the internal administration of bromide of potassium, has been attended with success. In the more advanced stages, especially when there is much oedema, free scarification of the mucous membrane, and frequent inhalations of warm soothing vapours and steam, may afford the most marked relief. If the dyspnoea becomes urgent, tracheotomy must be performed. It is true that from the nature of the malady there is often but little hope of a successful result; at the same time there can be no doubt but that by the operation a chance of prolonging life is afforded that could not otherwise be obtained; and that by it at any rate the last hours of the patient may be rendered comparatively free from suffering.¹

It may be worthy of remark that, apart altogether from any such serious affection as that thus described, it not unfrequently happens that in cases of erysipelas of the

¹ A fatal result ensued in 10 out of 15 cases of tracheotomy performed on account of erysipelatous laryngitis which have come under Mr. Durham's observation, or of which he collected particulars; in 5 cases the patients made good recoveries.

scalp and face there is some soreness of the throat, slight difficulty of breathing, and some alteration of the voice, such as weakness or hoarseness.

DIFFUSE CELLULAR LARYNGITIS. ACUTE ŒDEMATOUS LARYNGITIS.

Diffuse inflammation of the areolar tissue of the larynx is a comparatively rare but very formidable malady. It corresponds to the diffuse cellular inflammation not unfrequently met with in other parts of the body; but it is especially dangerous on account of the impediment to respiration and swallowing to which from its situation it necessarily gives rise. It is probably closely allied in nature to erysipelatos inflammation, from which, however, it differs in the fact that in it the submucous tissue is primarily attacked, and the mucous surface is left free, or only becomes secondarily affected. In erysipelas, on the other hand, the mucous surface is first affected, and the submucous tissue is only secondarily or concomitantly involved.

Diffuse cellular laryngitis may either occur in association with previously existing diffuse cellular inflammation of the neck, in which case it seems to form a part of the more general affection; or it may commence in or about the submucous tissue of the pharynx and larynx, and thence spread through the neck generally. In some instances, however, it may cause death from suffocation or exhaustion before any considerable extension to other parts can have taken place.

In this malady the appearance of the local affection is usually preceded, and its onward progress is invariably attended by more or less severe constitutional disturbance, and especially by great general depression. At the onset the patient often complains of having felt unwell for some days, and of having suffered from headache, lassitude, lowness of spirits, and other febrile symptoms. Soreness of the throat, at first slight, but rapidly becoming severe, is noticed early; and rigors soon occur. As the malady progresses breathing becomes impeded; and a sense of weight and oppression at the chest is complained of. There may be slight hacking cough, attended by the expectoration of a little whitish glairy mucus. The soreness of the throat increases; the fauces and tonsils become much swollen, and of a dusky red colour; and sometimes ulcerated patches appear upon them. Somewhat later the glands behind and below the jaw become enlarged; the neck becomes painful; and the mouth can only be opened with difficulty. The throat is tender when external pressure is made on one side or both. Occasionally a constant and profuse discharge of saliva takes place. Still later, the neck becomes swollen, and the swelling extends and increases; respiration is more and more impeded; and swallowing is rendered almost or quite impossible. The patient sinks into a typhoid condition, and dies exhausted; or, as perhaps more frequently happens, he is killed by a process of slow asphyxiation. In some cases, however, a sudden paroxysm of spasmodic dyspnoea proves fatal at a comparatively early period in the progress of the malady; and in others, the laryngeal oedema increases very rapidly, and causes speedy suffocation. Either of such results may ensue before any considerable, or even any perceptible, general swelling of the neck has taken place.

The swollen and œdematous condition of the upper part of the larynx may generally be easily ascertained by digital exploration, and the impression conveyed by the finger has been likened 'to that which is given by touching the tonsils.' In the earlier stages and less severe forms of the malady, laryngoscopic examination to some extent is comparatively easy; and the mucous membrane of the upper parts of the larynx may be seen to be distended and swollen. Dr. Mackenzie thus describes the appearances as seen by the laryngoscope. 'The colour of the mucous membrane is generally light red. The epiglottis has the appearance of a semi-transparent roll-like body or ridge, or, losing its normal contour altogether, it presents two round red swellings pressed against each other. It is often merely erect and tense. It is this condition of the epiglottis which explains the pain and difficulty accompanying the act of swallowing. In many cases the swollen epiglottis blocks the view of the interior of the larynx. Occasionally, however, the ary-epiglottic folds appear distinctly as two translucent folds, which almost meet over the entrance to the larynx,

and often touch each other in the median line at each effort of inspiration. It rarely happens that the vocal cords themselves are infiltrated.¹

On *post-mortem examination* extensive inflammatory œdema of the submucous tissue of the larynx and neighbouring parts is invariably found. In some cases one side is much more affected than the other. When cut into, the areolar tissues present an infiltrated, and sometimes more or less sloughy, appearance. The infiltration is serous, seropurulent, or purulent in character, according to the period at which death has occurred, and the circumstances under which it has taken place. The tissues of the neck are found in many cases to be infiltrated to a greater or less extent with serous, seropurulent, or fibrinous exudation. In cases in which there has been much swelling, they often present almost a brawny consistency. Sometimes the infiltration extends upwards behind the pharynx, sometimes downwards alongside the trachea and œsophagus, even into the mediastina. Occasionally the infiltration in the neck is purulent in character, and in some instances the areolar tissue is sloughy and putrid.

Treatment.—The same general treatment is required as that recommended in erysipelatous laryngitis. But in this malady local applications of nitrate of silver, &c., are far less likely to prove efficacious. The swollen parts should be freely and deeply scarified at a comparatively early period, and the scarification should be repeated without hesitation from time to time according to circumstances. After the scarification warm soothing vapours should be frequently, or almost constantly, inhaled for a time. At a subsequent period the spray of astringent solutions may be inhaled with advantage. Further, in cases in which the neck is much swollen, it may be desirable to make careful but free incisions into it, not only to evacuate pus or to allow of the escape of serous effusion, but also with the view of diminishing the tension and consequent pressure upon the trachea and œsophagus.

If such means fail to afford relief, and the dyspnoea is urgent, tracheotomy must be performed, although the difficulties attending the operation may be great, and the chances of a successful result may appear small.

An excellent illustration of the value of tracheotomy in cases of this kind occurred some years ago in the practice of Mr. Pollock at St. George's Hospital.

The patient (a butcher, aged 43) was admitted with severe and extensive diffuse cellular inflammation of the neck. Urgent laryngeal symptoms soon supervened. Tracheotomy was performed, and the patient made a good recovery in a comparatively short space of time.¹

OTHER FORMS OF LARYNGITIS. EXANTHEMATOUS LARYNGITIS; TRAUMATIC LARYNGITIS, &c.

Consecutive inflammation of the larynx occasionally occurs in the course of various general maladies, other than those the laryngeal complications of which have been already described in detail. It is especially liable to occur in measles and typhoid fever. It is more rarely met with in smallpox and typhus, and still more rarely in scarlet fever.

The *laryngitis of measles* is catarrhal in character, and in most instances appears soon after the nasal catarrh. Respiration may be more or less embarrassed; and sometimes there is remarkable harshness of the voice, and frequent harsh cough. In young children the breathing is occasionally stridulous, and the cough ringing. The consequences are very seldom serious; but it is well to bear in mind that they may possibly become so. In some rare instances, dangerous, and even fatal, œdema of the larynx has ensued; and in some the œdema has persisted after the general symptoms have subsided. In such cases the laryngeal symptoms have appeared early, and from the first have been very acute. As a general rule, the mucous membrane of the larynx is simply affected in a manner corresponding to the cutaneous eruption;

¹ See *Lancet*, September 1863, p. 276.

and the symptoms subside as the eruption disappears. It is not often that any local treatment is necessary or desirable, beyond the application of warm poultices and fomentations to the neck, and the inhalation of warm soothing vapours. If, however, the symptoms are severe and persistent, the same treatment may be required as that recommended in cases of acute catarrhal laryngitis (see p. 669).

The *laryngitis of typhoid fever* is ulcerative and destructive in character.¹ It may either commence during the earlier or middle stages of the malady, concomitantly with the ulceration of the intestinal glands and mucous membrane, and speedily give rise to serious symptoms, or even to a fatal result; or its existence may first become manifest during the period of convalescence and after all febrile symptoms have subsided. The ulcerations which occur during the earlier stages are generally situated either on the aryteno-epiglottidean folds, in the neighbourhood of the arytenoid cartilages, or, according to Rokitansky, about the lateral walls of the larynx. They may give rise to more or less severe functional disturbance—often to cough and difficulty of swallowing, and, somewhat less frequently, to difficulty of breathing. The difficulty of breathing usually corresponds to the amount of inflammatory œdema that may have occurred. It is sometimes difficult to determine how far the cough may depend upon laryngeal, and how far upon bronchial, affection. It is probable that in a large proportion of cases, if a patient survive the general malady, these ulcerations heal favourably, like the corresponding intestinal ulcerations. But in cases in which the symptoms become manifest at a comparatively late period in the course of the malady, or in which ulceration goes on insidiously, and perhaps almost unnoticed until seeming convalescence has taken place, the perichondrium and cartilages (and especially the cricoid) are very liable to be implicated to a greater or less extent. Under such circumstances the consequences are often very serious. Necrosis of the cartilages may result in association with typhoid fever, not only from gradual penetration of the ulcerative process, but also in some cases as an effect of some deep-seated inflammatory condition commencing in or about the cartilages themselves.

A remarkable instance came under Mr. Durham's observation in Guy's Hospital, while acting as Ward Clerk to the late Dr. Addison. 'A boy, ten years of age, had apparently recovered from typhoid fever. One morning he complained of pain in the throat. A day or two afterwards he expectorated some pus. The next day his neck was observed to be swollen and emphysematous. The emphysema rapidly spread over the whole body, even to the scrotum and penis, which became enormously and peculiarly distended. Two days later death occurred. On post-mortem examination a small ulcerated opening leading down to a necrosed portion of the cricoid cartilage was found below the glottis, on the right side. Through this opening evidently the air had escaped during expiration into the areolar tissue of the neck, and had thence spread over the body. No other case of any kind has ever come under his observation in which the emphysema was so extensive and so general. The cavities as well as the superficial parts of the body were affected; and indeed it appeared probable that death had resulted from the impediment to respiration caused by the intra-thoracic emphysema.'

In a certain proportion of cases in which the symptoms are not severe, recovery may take place without any local treatment beyond the application of warm fomentations to the neck, and the inhalation of warm soothing vapours. The general treatment of typhoid fever must, of course, be carried out. In all cases, however, in which the symptoms are urgent, tracheotomy should be performed. It is undeniable that the statistical results hitherto obtained do not appear to be

¹ This affection is the *laryngo-typhus* of the Germans. It appears to have been first definitely and fully described by Louis, in whose treatise, entitled *Recherches sur la Fièvre typhoïde* (Paris, 1841), much valuable information on the subject is contained. Trousseau especially refers to the laryngeal complications of typhoid fever, and gives some excellent illustrative cases in his *Clinique médicale*, vol. i. p. 299; Paris, 1868. (Homel, Rokitansky, Wilks (*Med. Times and Gaz.*, 1862, p. 276), and others also fully discuss the pathological history, or give examples of typhoid disease of the larynx. The appearance of the ulcers is so characteristic that Louis says that, if observed in a patient who had died of some acute disease, they would be sufficient to indicate almost certainly that the affection had been typhoid fever. *Op. cit.* p. 321.

very encouraging.¹ At the same time the success which has resulted in some cases justifies resort to this operation, which indeed alone offers any chance of safety.

In the *laryngitis of small-pox* the mucous membrane of the larynx is affected in a manner which varies with the stage of the malady, and corresponds more or less closely with the more obvious external appearances. In the earlier stages, pustules may arise analogous to those observed on the cutaneous surface. Neumann, Türck, and Krishaber all state that they have seen, by aid of the laryngoscope, true variolous pustules surrounded by circumscribed inflammatory areolæ, upon the true vocal cords as well as on other parts of the laryngeal mucous membrane. The symptoms are hoarseness, cough, and more or less uncomfortableness or pain about the larynx. About the eleventh or twelfth day, at the period at which swelling of the face and extremities is especially liable to occur, œdema of the larynx may come on; and respiration may be more or less seriously, or even fatally, impeded. During the still more advanced stages of the malady, at or about the period at which abscesses are occasionally formed in other parts, perichondritis and subsequent necrosis of cartilage, with all the attendant symptoms and dangers, may ensue.

In *scarlet fever* the larynx may either be affected during the earlier stages by extension of inflammation or inflammatory œdema from the pharynx; or, in common with other parts, it may become œdematous as the result of consecutive kidney disease. The true scarlet fever eruption very rarely indeed, if ever, invades the larynx. The local treatment necessary in each case may be gathered from what has been already stated in regard to similar affections arising in connection with other maladies.

It may here be remarked that in *Bright's disease* the larynx may participate in the general œdema, and this may prove dangerous or fatal from the obstruction to respiration to which it gives rise.

Gouty laryngitis may possibly be considered to possess small claim to be described as a distinct form of disease. But it is worthy of remark that in gouty subjects chronic laryngeal affections are by no means uncommon. Sometimes they are very troublesome, and even distressing to the patient; and they are always difficult to treat successfully unless the existence of the general condition upon which they depend is fully recognised, and modified by appropriate constitutional remedies. In many cases they occur in association with gouty bronchitis and tracheitis, but even in some of these the laryngeal symptoms may attract most attention, and give rise to most trouble and danger. In certain rare instances acute laryngitis of very formidable character has been observed to occur in connection with an attack of gout.

Traumatic laryngitis has been already described in the chapters treating on the various injuries—as wounds, blows, burns, &c. from which it may result (see article on INJURIES OF THE NECK).

NON-MALIGNANT TUMOURS. POLYPI.

New growths in the larynx were formerly supposed to be of very rare occurrence; and indeed, except in some few and very remarkable instances, their presence could only be determined on post-mortem examination. Since the laryngoscope has come into use, however, a large number of cases have been recorded; and many more at present unpublished have come under observation, in which growths in the larynx have not only been recognised during life, but have been successfully removed by operation. There is probably no other class of cases in which the value of the laryngoscope has been so signally demonstrated. It would appear not unlikely that this circumstance, together with the interest naturally attaching to cases of this kind,

¹ I find that out of 35 recorded cases in which tracheotomy was performed on account of 'typhoid' disease of the larynx, in 24 death ensued. In 11, life was saved; but in several of them the voice was permanently impaired, and the cannula could never be dispensed with.

and the attention consequently attracted to them, has been the means of leading to the now prevalent idea that they are even more common than is actually the fact. They are certainly more frequent than was formerly supposed; but they nevertheless constitute only a very small proportion of the affections of the larynx that come under every-day observation. Krishaber states that such growths are to be 'met with in two or three per cent. of the cases of maladies of the larynx exclusively local and chronic.'¹ My own experience would lead me to the conclusion that they are much less frequent even than this.

The new growths in the larynx met with in different cases vary in character, size, and precise situation, and also, to a corresponding extent, in the symptoms to which they give rise and in the degree of danger they immediately involve. They may occur at any period of life, but are most common between forty and fifty; in some instances they are congenital;² in others they do not appear until advanced age. They are rather more common in the male. No satisfactory conclusion has yet been arrived at as to the local or general determining causes of their appearance in the majority of cases, but long-continued congestion following catarrh is probably one of the most common. The professional use of the voice also is said to be highly favourable to their development. The larger proportion of laryngeal tumours are non-malignant. Papillomata are certainly the most frequent. Dr. Mackenzie, out of 100 cases, found 67 of this nature; and, of 66 cases of growths of all kinds, Cohen noted 48. Fibromata stand next in numerical order. Cystic tumours are occasionally observed springing from the epiglottis. Myxomata are very rarely met with. Mackenzie has only twice observed an angiomatous growth, and only one case of lipoma is at present recorded. In some instances they may be simply the thickened elevations of surface, or the 'vegetation-like' granulations of phthisical laryngitis. Such excrescences, however, should not be considered as true growths. Distinct tumours, however, are occasionally found in phthisical and syphilitic patients, and Cohen believes both these diseases predisposed to their development.

Papillomata or warty growths constitute a very large proportion of the new growths met with in the larynx. In structure and appearance they bear a general resemblance to growths of similar nature found in other parts; they may occur either as little warty elevations, consisting of comparatively few, and sometimes almost acuminate papillæ, or as closely packed and multitudinous villous or filipendulous outgrowths, or as densely massed 'cauliflower-like' agglomerations of elongated and enlarged papillæ, rounded or flattened at their extremities. They most frequently, perhaps, spring from the mucous membrane of the anterior part of the larynx, somewhere near the insertion of the true vocal cords. In many instances they take origin from the boundaries of the ventricles, and in some from the true vocal cords; but they may arise from almost any part of the laryngeal mucous membrane. As a rule, they are multiple in origin, and spring up simultaneously or successively in several different places. Sooner or later, they more or less completely coalesce, so as to form one or many distinct masses. Some idea of the general appearance presented by growths of this kind may be conveyed by fig. 152, which is taken from a preparation in the Museum of Guy's Hospital.³ The growths in this case form a single mass, which cannot be considered as otherwise than of moderate dimensions when compared with those met with in many other instances. It was sufficiently large, however, to lead to a fatal result. In some cases these growths increase very rapidly, and to such an extent as to fill altogether, and sometimes even to distend the cavity of the larynx. They are usually pink in colour, but sometimes bright red.

¹ *Op. cit.* p. 730.

² One case came under Mr. Durham's observation in which it was evident that the growth had commenced before, or immediately after, birth. Another case, also congenital, is recorded by Mackenzie (*Path. Trans.*, 1865, p. 38). Three are recorded by Gibb (*op. cit.*), and several are quoted by Causit in his *Etude sur les Polypes du Larynx chez les Enfants*. Paris, 1867. More recently Dr. Arthur Eddis has related an interesting case in the Transactions of the Obstetrical Society, vol. xviii.

³ Preparation No. 1703.

A very remarkable instance is recorded and figured by Bruns.¹ In another case of the same kind, of four or five years' standing, in which Mr. Durham removed the growths after having laid open the larynx, it appeared remarkable that such a mass as was removed could ever have found room in so small a space.² The laryngeal mucous membrane was literally covered by growths, which varied in size and density. The patient nevertheless made a rapid recovery, and has now a very fair voice.

In most cases the rapid increase of the growths, or the general inflammatory condition which may arise in association with their presence, and the consequent obstruction to respiration, render tracheotomy necessary, or, without this operation, lead to a fatal result at a comparatively early period. But in some instances patients suffering from laryngeal growths of this kind have been known to live for years. In such cases, it is probable that the larynx has been sufficiently cleared for breathing purposes by the detachment and expectoration of portions of the growth from time to time during coughing. Türk records a case in which the whole growth appears to have thus been got rid of.³

According to some observers, it would appear that these papillomatous growths occasionally undergo a process of pulpy or caseous degeneration.⁴ In such cases it is easy to understand that they may become broken down and expectorated.

FIG. 152.—Papilloma of Larynx springing from border of left ventricle. Larynx opened in front.

FIG. 153. Pedunculated Fibrous Polypus of the Larynx arising near the anterior extremity of the right ventricle of the larynx.

Fibromata or fibrous growths are met with in the larynx much less frequently than the papillary growths above described, but numerous instances are on record.

These growths are usually smooth on the surface, hemispherical, globular, or pyriform in shape, and on laryngoscopic inspection they appear somewhat paler in colour than the mucous membrane of the surrounding parts, but are sometimes brightish red. In substance they are more or less firm and compact. In structure, they resemble growths of similar nature developed in other parts; as a rule, they are solitary; they may be sessile with broad base, or pedunculated. If pedunculated, the pedicle is generally less firm and more vascular than the growth itself. In a large proportion of cases these growths are comparatively small, and do not each exceed the size of a pea; but they may attain considerable dimensions. In an instance referred to by Rokitanaky, the growth was as large as a pigeon's egg.⁵ A pedunculated fibrous growth of medium size is represented in fig. 153, which is taken from a specimen in the Museum of Guy's Hospital.⁶

⁵ *Zeitschr. d. k.k. Gesellsch. d. Aerzte z. Wien*, 1851, quoted by Krishaber. *Op. cit.* p. 730.

⁶ Preparation No. 1703¹⁰. Tracheotomy had been performed in this case; and the patient

The larger pedunculated growths generally take origin from one or other of the true vocal cords, or from some immediately adjoining part of the ventricular wall—and in the latter case most frequently near the anterior extremity of the ventricle. They may, however, arise in other parts of the larynx, but they very seldom do so; in scarcely any instance has a growth of this kind been found connected with the mucous membrane covering the arytenoid cartilages.

Adenomatous or glandular growths are occasionally but rarely met with in the larynx. As a rule, they take origin from the mucous membrane covering the arytenoid cartilages, the aryteno-epiglottidean folds, or the base of the epiglottis,—or, in general terms, from those parts of the mucous membrane which are naturally most abundantly supplied with glandular structures. In this respect they differ remarkably from all other laryngeal growths of non-malignant character. They consist essentially of enlarged and hypertrophied glands and follicles, surrounded by more or less thickened submucous connective tissue and mucous membrane. Occasionally they appear to contain adenoid structures of new formation. They may be sessile or pedunculated. When sessile (localised glandular hypertrophy of the mucous membrane) they often present a more or less lobulated appearance; and in some instances they attain very considerable dimensions.¹ When pedunculated they are usually more or less pyriform or globular, and their peduncles are proportionately longer than those of the fibrous polypi. When seen during life, by aid of the laryngoscope, these growths are generally of a deepish red colour, but they often become pale as they advance in age. They are remarkable for the rapid changes in volume they are liable to undergo under various circumstances. Thus a slight attack of catarrhal laryngitis is almost sure to be attended by speedy and considerable increase in the size of the growth, which may, however, again become smaller as the inflammatory condition passes off.

Cystic tumours of various kinds are met with from time to time in the larynx; but instances are comparatively rare. In some cases they may possibly result from the degeneration and breaking down of myxomatous growths, as suggested by Cornil and Ranvier;² but more frequently, probably, they owe their origin to causes corresponding to those which lead to the development of similar cysts in other parts. In some cases their contents are serous, or serosanguinolent; in others mucous, albuminous, or synovial in character. They may occur in almost any part of the larynx, but are most common on the epiglottis, and in some cases attain considerable size.³

An interesting, and I believe almost unique, example of mucous cyst connected with the posterior aspect of the epiglottis, came under the care of Dr. Wilks and Mr. Durham in Guy's Hospital some few years ago. 'The patient, a delicate boy eleven years of age, had suffered two years previously from a severe attack of sore throat, and ever since had experienced more or less difficulty in swallowing. This difficulty gradually increased. His voice soon became affected, and by-and-by he began to suffer from frequent and severe attacks of dyspnoea, which often came on during sleep. On laryngoscopic examination, the epiglottis was not to be seen presenting its ordinary form; but instead of it there appeared a large rounded swelling, projecting downwards and backwards, and completely covering in and concealing the glottis. The tumour was pale in colour, shining, and somewhat translucent in appearance. It could be just reached by the finger, and was elastic, but very tense to the touch. Feeling certain that it contained fluid, Mr. Durham made a free incision into it, by means of a curved, sharp-pointed bistoury. A sudden gush of thick, glairy, muco-purulent matter took place; and after the momentary dyspnoea which occurred had subsided, the patient was relieved of all the symptoms from which he had before suffered so severely. He made a rapid recovery, and left the hospital quite well. On examination laryngoscopically four years

had for a long time been comparatively comfortable, but voiceless. One day the tube got displaced. Spasm of the larynx, conjoined with the mechanical obstruction caused by the growth, proved immediately fatal.

¹ See case quoted by Ehrmann, *Histoire des Polypes du Larynx*. Strasbourg, 1850.

² Quoted by Krishaber.

³ See a remarkable case described by Gibb (*op. cit.* p. 154), in which the tumour apparently sprang from the right ventricle, and filled nearly the whole glottis.

afterwards (as well as from time to time in the interim), no indications of any return of the disease, nor indeed any very clearly perceptible mark of the incision, could be discovered.¹ A case of somewhat similar kind is recorded by Delorme, in which two cysts, with glairy albuminous contents, were found on the posterior aspect of the epiglottis of a man, forty years of age, who died asphyxiated.²

It is worthy of remark, perhaps, that *true hydatid cysts* are stated to have been found in the larynx in some few very exceptional cases.³

A few instances of *cartilaginous and osseous growths* in the larynx are on record.⁴

Besides the growths of the various kinds thus described, others of mixed form and character are occasionally met with in the larynx. Thus the fibrous, fibrocellular, and glandular elements may vary in relative proportion in such manner and to such extent as may render it impossible to assign the particular growth under examination to any definite class. And so again some growths which superficially appear papillomatous may have firm fibrous bases. And, further, the condylomata of syphilis, the thickened elevations of phthisis, and the small protuberances resulting from localised chronic inflammation in some cases can hardly be distinguished from what more properly, perhaps, ought to be regarded as 'new growths' in the strictest acceptance of the term.

A very interesting specimen was almost accidentally met with some short time since in the post-mortem room at Guy's Hospital, in which there was extroversion of the mucous membrane of the left ventricle of the larynx. Fig. 154 conveys a somewhat feeble idea of the appearance presented. The extroverted mucous membrane could be easily replaced in its proper position; and when this was done there was nothing abnormal in the appearance of the larynx. The patient had had no laryngeal symptoms.⁵

FIG. 154.—Extroversion of the Mucous Membrane of the Left Ventricle of Larynx, simulating laryngeal polypus.

MALIGNANT TUMOURS OF LARYNX.

Cancerous growths in the larynx are for the most part *epitheliomatous* in character; but instances of *medullary cancer* affecting the larynx are not wanting. *Scirrhus* cancer is still more rare.

Epithelioma of the larynx generally commences on the pharyngeal aspect of the mucous membrane covering the arytenoid or cricoid cartilages, and subsequently invades the interior of the larynx. But in some instances it commences inside; and in such cases, as a rule, it first appears on the ventricular bands or on the mucous membrane of the posterior and lower part of the larynx over or near the internal surface of the cricoid cartilage, in the form of small irregular nodules, which gradually increase in size and soon ulcerate. The distinctive features of advanced epithelioma of the larynx, as seen by aid of the laryngoscope, have been already described (see p. 682).

⁵ The case is fully described by Dr. Moxon, *Trans. Path. Soc.* 1868, p. 65. The preparation is in the Museum of Guy's Hospital. Preparation 1083.

The *symptoms* to which 'new growths' or 'polypi' in the larynx give rise vary in character and severity with the dimensions and precise relations of the particular growths under observation; and also with the intensity of the inflammatory condition which in many cases may be excited by their presence, or at any rate may be sooner or later associated with it.

Difficulty of breathing, alteration or extinction of the voice, cough, and, it may be (especially in the case of cancerous growths), difficulty of swallowing; these are the symptoms—as indeed they are also the symptoms, varying only in intensity and urgency—in all serious affections of the larynx, as well as in some other maladies in which the larynx is only indirectly affected. It is very rarely indeed, if ever, that any one of these symptoms manifests such peculiarities as may be considered to indicate the presence of a 'new growth.'

In many cases when the patient first comes under observation the difficulty of breathing is so urgent, or becomes urgent so speedily, that tracheotomy must be performed before any exact diagnosis can be made. The difficulty of breathing may depend either upon the mechanical obstruction caused by the growth, or upon spasm of the larynx excited by an incidental contact of the growth with some unaccustomed or already irritated part of the highly sensitive boundaries of the glottis. A growth may exist for a long time almost harmlessly, moving in correspondence with the respiratory movements of the larynx, and then all at once may get into such position as to excite the most severe attack of spasmodic dyspnoea. This is especially likely to occur in the case of pedunculated growths. It may occur in other cases, if from any cause an attack of ordinary laryngitis should supervene; and it is always more likely to happen in children. Sessile growths by their gradual increase may gradually constrict the aperture of the glottis, and thus proportionately impede respiration, without giving rise, at least during their earlier stages, to any such suddenly serious and dangerous results as those thus indicated.

In the case of growths situated below the glottis, it may happen that expiration is almost as much impeded as inspiration.

In some cases, by means of the stethoscope placed over the larynx, a sound produced by the movements of the growth during respiration (the *bruit de drapau* of the French) may be detected.

The voice is affected to a greater or less extent in almost all cases; and if the growths are small, and situated on the vocal cords, the affection of the voice may be the only symptom of which the patient complains. The voice may be simply changed in tone and quality and become harsh; or it may have the 'cracked pot' or 'Punch' sound; or it may be reduced to a hoarse whisper; or it may be altogether extinguished. In some exceptional cases, the voice, at first seriously affected, has been noticed to improve to a certain extent with the increase of the growth.

In a considerable proportion of cases there is little or no troublesome cough. But if an attack of catarrhal inflammation should occur, the cough becomes especially distressing; and fits of spasmodic cough may be excited from time to time in any case in which a pendulous tumour is liable to get into obstructive position. Occasionally the patient becomes conscious of the presence of some cause of obstruction, and tries to 'cough it up.'

Slight mucous or mucopurulent expectoration may attend the cough: sometimes portions of the growths may be mingled with the expectorated material;¹ and, as already stated, in some exceptional instances, considerable portions and even the whole of the 'new growths' have been got rid of in this manner.

Among the various affections which may give rise to symptoms similar to those thus referred to as caused by the presence of new growths in the larynx, may be enumerated—chronic laryngitis with œdema; spasm of the larynx, from whatever cause; laryngismus stridulus; nervous aphonia; pressure upon the pneumogastrics

¹ It may be interesting, from an historical point of view, to quote the words of Ehrmann, writing in the year 1850:—'Il n'existe, il faut le dire, qu'en *seul* signe certain de l'existence de cette maladie; c'est l'expectation de quelques parcelles du polype.'—*Op. cit.* p. 31.

or the recurrent branches by tumours, aneurisms, &c.; retropharyngeal abscesses; pharyngeal polypi hanging down or projecting into the larynx, &c. It is, however, in the present day altogether needless to discuss in detail the distinctive differences that may or may not be presented by the symptoms in these several affections. In all cases in which time and opportunity are at command the diagnosis may be readily determined by aid of the laryngoscope. In cases, however, in which the symptoms are very urgent, whatever may be their cause, relief must be afforded and safety secured by tracheotomy or otherwise before any full inquiry can be entered upon: laryngoscopic examination may then be made under favourable circumstances at any convenient subsequent period. It occasionally happens, in the case of growths taking origin low down, that they almost disappear under the vocal cords or into the ventricles during inspiration, and only come thoroughly into view during expiration.

It is worthy of note that in some cases, particularly in children, who are difficult subjects for laryngoscopical examination, valuable, if not conclusive, indications may often be obtained by digital exploration. The effort at vomiting commonly excited during the introduction of the finger into the pharynx causes the larynx to rise momentarily, and thus to come within easy reach.

Treatment.—Measures should be adopted for the removal or destruction of all non-malignant new growths in the larynx as soon as practicable after their presence and probable character have been ascertained. For it may be asserted without fear of contradiction that no patient can be considered safe who has in his larynx a new growth of any considerable size—that is to say, unless his safety has been secured by tracheotomy. And small growths, as already stated, are liable to enlarge more or less quickly, and often unexpectedly; and even while still small they may favour the supervention of dangerous inflammation.

In some cases it is absolutely necessary, and in others it may be desirable, to perform tracheotomy before proceeding to any further operative measures. Very many cases, however, have now occurred in which, without tracheotomy, growths have been removed from the larynx, not only with the best ultimate results, but also without having involved the patient even temporarily in any serious risk.

The advisability of performing tracheotomy as a preliminary measure must be determined by the urgency of the symptoms, and the probable difficulties and dangers of the proceedings about to be carried out.

A great variety of different methods has been devised and adopted for the removal of growths from the larynx. They may be divided into those in which the operation is performed by aid of the laryngoscope through the mouth and natural passages, and those in which access is first obtained to the interior of the larynx by means of incisions in the median line through the skin, cartilages, &c.

In deciding upon the course to be pursued, it is necessary in every case to take into consideration not only the size, precise situation, and character of the growth, but also the age, development, and condition of the patient, together with his general and special powers of endurance. If success is not attained by the method first adopted, another may be tried.

A. Endo-laryngeal Operations.

1. *The application of caustics and powerful astringents to growths in the larynx* may be accomplished by the several methods already described (see p. 663); in the case of small isolated papillary growths, such applications, several times repeated, are not unlikely to prove efficacious.

2. Small fibrous, fibroid, and fibro-cellular growths, and small or large papillary growths, may, in many cases, be successfully seized by means of properly adapted *forceps*, and either *torn off* and removed in mass, or so *crushed* as to lead to their destruction. It is always desirable to warm all laryngeal instruments in order to prevent, as far as possible, unnecessary irritation. As a rule, it is not safe to give

chloroform. In the case of multiple growths, the repeated use of the forceps is often necessary. Portion after portion may be removed either at the same sitting, or during a series of sittings at intervals, according to circumstances. This method is especially advocated by Mackenzie;¹ and the laryngeal forceps which bear his name (fig. 155) are, I believe, the most generally applicable, and therefore the best of all the instruments yet devised for such purposes. They can be fitted with horizontal or perpendicular blades. Forceps made upon the principle illustrated in fig. 156 are also very efficient. Some of these forceps are made to open laterally, and others antero-posteriorly, like those represented in the figure. In some cases ordinary laryngeal forceps, such as those figured and described in the chapter on Foreign Bodies in the Larynx, have been used with perfect success.

Fig. 155.—Mackenzie's Laryngeal Forceps.

3. For the removal of laryngeal growths by the *Wire Snare* it is necessary to employ a slender and appropriately curved instrument carrying a wire loop, which can be quickly and easily drawn home when once it has been made to encircle the growth. The instrument successfully used by Dr. Walker of Peterborough in the first case in which a laryngeal growth was removed from the larynx during life in this country, was a modification of Gooch's double cannula.² But the double tube is cumbersome and altogether unnecessary. Gibb's 'Laryngeal Escraser'³ is a far more perfect instrument—indeed, nothing could be better adapted for its purpose, unless it be some such modification as that suggested by Dr. George Johnson.⁴ These instruments bear a general resemblance in construction and mode of working to Wilde's Aural Polypus Snare, and Hilton's Nasal Polypus Snare; but they are, of

Fig. 156.—Laryngeal Forceps, opening antero-posteriorly.

course, different in shape and more slender. In using this instrument the wire loop is made to encircle the growth, and then pulled tightly home. The growth is then forcibly pulled or twisted from its attachment, and, as a rule, is brought away in the loop. This method is strongly advocated by Sir D. Gibb,⁵ and Dr. George Johnson.⁶ It is especially applicable in cases in which the growths project in such manner and direction as to render them easily caught, and in which they are soft or pliable in texture, and not very large. Dr. Mackenzie has, however, pointed out the possibility of the wire being displaced, and thus missing the growth. He has devised and successfully used a wire snare concealed in a loop of metal, which can be slowly tightened by means of a cog-wheel turned by the index-finger. Professor Stoerk was

⁶ *Op. cit.* p. 173 *et seq.*

the first to use the metal guard; but his instrument has a circular knife in place of the wire, on the principle of the guillotine.

4. *The galvanocautic method* was first practised by Middeldorpf, and has since been adopted by Voltolini, Türk, Bruns, and others. It has been still more recently recommended by Dr. Reichel of Breslau.¹ This method consists in encircling and cutting off the growth by means of a platinum wire, which is so arranged in an appropriate carrier that when in position it can be intensely heated by means of a galvanic battery with which it is connected. The difficulties of this method are sufficiently obvious, and they, together with certain other practical objections to it, are clearly and forcibly stated by Bruns,² after some experience of its use. Its advantages in certain cases are equally obvious; and it would appear to be especially applicable in cases in which single fibrous growths exist, the peduncles of which are too strong to permit them to be safely torn away by means of the snare or forceps. A touch of the heated wire may be sufficient to dispose of small papillomatous growths.

5. *The knife*, properly curved and guarded, or the *laryngeal scissors*, may be used for the separation of firmly-attached growths which may have been seized but cannot be pulled off by the snare or forceps. Such means were adopted in several of the cases successfully treated by Bruns.³ Several different forms of laryngeal guillotine have been devised. Of these Matthieu's is probably the best. It has been used with success in several cases.

6. *Simple puncture* by the guarded bistoury or some specially contrived instrument (such as Mackenzie's laryngeal lancet) has proved completely efficacious in several instances in which the growths were cystic in character; and in such cases this method may be recommended. If in any case the cyst should fill again, it may be desirable on a second occasion to remove a portion of the cyst wall, or at least to make a more extensive incision than the previous one.

It is scarcely needful to add that all these several methods of removing laryngeal growths require during their execution the guidance afforded by the laryngoscope.

B. Extra-laryngeal Operations.⁴

In certain cases in which the growths are numerous, or very large, or single but firmly attached, and in those cases again in which the patients are young, and unable to bear the introduction of instruments through their narrow natural passages, the easiest, most certain, and at the same time the safest method of operating consists in laying open the cavity of the larynx by external incision, and then removing the growths by scissors, écraseur, or galvano-caustic wire. The results of experience⁵ encourage the further and more confident adoption of this procedure in special cases. It affords opportunity for the more immediate, complete, and effectual removal of the growths than can be obtained in any other manner. It is by no means difficult of execution, nor does it usually involve any very great risk. Such bleeding as may occur can be readily checked, for all the parts are fully exposed; and freedom of respiration may be secured by the preliminary performance of tracheotomy—if, indeed, this operation have not previously been rendered necessary.

A good illustration of the success attending this method is afforded by the case of a girl, thirteen years of age, under Mr. Durham's care some years since in Guy's Hospital. Tracheotomy had been performed four years previously on account of the urgent dyspnoea

¹ *Klinische Wochenschrift*, No. li. 1860. Berlin.

² *Die Laryngoskopie und die laryngoskopische Chirurgie*, p. 144, et seq. Tübingen, 1865.

³ See Table, *op. cit.* p. 254.

⁴ It is worthy of note, that the first recorded operation of this kind was performed in the year 1844 by Ehrmann, who, without the aid of the laryngoscope (not then in use), diagnosed the existence of growths in the larynx from the symptoms and the appearance of portions in the sputa. He was justly so confident of the correctness of his diagnosis, that he boldly opened the larynx by median section, found the growths, removed them, and cured his patient. *Laryngotomie dans un cas de Polype du Larynx*; Strasbourg, 1844. Also *op. cit.*

⁵ See especially the excellent treatise of Dr. Charles Planchon, *Faits cliniques de Laryngotomie*; Paris, 1869. In this treatise a large number of illustrative cases are given.

from which she then suffered. On laryngoscopic examination, masses of warty growths were distinctly seen. These were removed by the scissors after exposure of the laryngeal cavity by section through the thyroid cartilage, crico-thyroid membrane, and other structures. Nitrate of silver was freely applied to the bleeding surfaces. The growths had occupied the whole cavity of the larynx. The divided parts were brought together. The patient made a speedy recovery, and the tracheotomy cannula, which she had worn for four years, was removed ten days after the operation. Three or four years after the operation she was in good voice, and no appearance could be discovered of any recurrence of the growths.¹ In two other cases the results have been equally satisfactory.

A remarkable case is recorded by Balassa of Pesth. The patient, a young woman, twenty-one years of age, had suffered from more or less difficulty of breathing, and had been aphonic for more than two years. On laryngoscopic examination growths in the larynx were seen. Balassa laid open the larynx by section through the thyroid cartilage, and removed five portions of new growth. The patient made a good recovery, and her voice returned. Less than a year afterwards, she again lost her voice, and experienced increased difficulty in breathing. Balassa a second time opened the larynx through the thyroid cartilage in the situation of the old cicatrix. Three or four portions of new growth were removed. The patient again made a good recovery; and, as the result, was altogether relieved of her dyspnoea, and regained her voice.²

Extra-laryngeal operations, however, should only be attempted after other less severe methods have failed, or when life is in danger from dysphagia or suffocation.

In operations of this kind the thyroid cartilage or the thyro-hyoid or crico-thyroid membrane may be divided after Malgaigne's method. It is desirable to avoid, if possible, cutting through or otherwise damaging the cricoid cartilage.

MM. Prat and Follin have each succeeded in removing tumours from the larynx after having divided the thyro-hyoid membrane and superficial structures by transverse incision.³ The objections to this method, arising principally from the necessary section of the hyoidean muscles, as well as from the imperfect extent to which the cavity of the larynx is exposed, are sufficiently obvious.

In the case of epitheliomatous and other cancerous growths, it would appear to be worse than useless to attempt removal, without first fully opening the larynx and exposing the whole extent of the morbid structures. Whether any such attempt is justifiable the circumstances of the case must decide. As a general rule tracheotomy becomes necessary sooner or later; and it is probable that, when once the character of the malady is recognised, the earlier the operation is performed the better.

Extirpation of the larynx.—The removal of the entire larynx, including the lower portion of the epiglottis, was first performed by Billroth in the year 1873. It had been suggested as a practicable operation, however, nearly twenty years before this. In 1870 Czerny,⁴ by experiments on dogs, proved that the operation might be successfully carried out. In Billroth's case, in addition to the cricoid and thyroid cartilages and both arytenoids, the two upper tracheal rings and the lower portion of the epiglottis were removed. In one case, in addition to the entire larynx, the hyoid bone, and part of the tongue, and both submaxillary glands were removed.⁵ The patient recovered from the operation and lived several months afterwards, ultimately dying from a recurrence of the original disease (carcinoma) in the cervical lymphatic glands.

Dr. Foulis of Glasgow⁶ was the first to perform the operation in this country. In his case a papilloma had been twice completely removed by extra-laryngeal methods, and, after an interval of nearly sixteen months, had again so increased in size as to necessitate the removal of the larynx. Dr. Foulis was, however, able to save the upper cornua of the thyroid, and a portion of the arytenoid cartilages. This patient, however, died within a year and a half from pulmonary phthisis. Dr. Foulis describes the operation as follows:—‘A single vertical median incision from

¹ See *Guy's Hospital Reports*, 3rd series, vol. xii. p. 541.

⁶ *Lancet*, October 1877.

the hyoid bone to the second ring of the trachea exposes the front of the larynx. The two sides of the cartilaginous box are then freed from the muscles quite back to the gullet. Up to this point the larynx is not opened, and no blood can escape into it. The larynx is then separated from the trachea by a transverse cut, the trachea having been previously transfixed and held forward with a sharp hook. A large syphon tube of vulcanite, fitting the trachea, is put in to keep out the blood and permit free respiration. If this is neatly and carefully done, there is no need of preliminary tracheotomy and use of Trendelenburg's tampon, which has the disadvantage of largely increasing the length of the wound; while in Billroth's case, at all events, it was not found to facilitate matters to any extent. If there is much oozing, something may be done by adopting Ross's plan of lowering the head of the patient, so that the flow of blood is in the direction away from the trachea. The upper and posterior attachments of the larynx are next cut, care being taken in separating the gullet and pharynx to keep the edge of the knife close to the cartilages so as to avoid button-holing the gullet. It might be well to mop the raw surface out with a solution of chloride of zinc (30 gr. to the ounce) at the close of the operation; but it is not advisable to irrigate the wound in any way afterwards, on account of the gulping and "irritation which it sets up." When the wound has fairly healed, Gussenbauer's¹ artificial vocal apparatus should be introduced. In Billroth's case this was introduced, on the twenty-first day the patient being able to speak in a loud monotonous artificial voice. Dr. Mackenzie² gives a very valuable table of the cases hitherto recorded. It appears that out of nineteen patients who had been subjected to entire or partial removal of the larynx, nearly half died within the first fortnight. In seven others, recurrence of the disease took place at periods varying from three to ten months. These results are not encouraging, for there is certainly a very great immediate risk, and it is, moreover, at present difficult to rightly estimate the chance of life without resorting to operation.

Trendelenburg's laryngeal tampon consists of an india-rubber belt which encircles the lower end of the tracheotomy tube. The belt is inflated (but not too fully) by means of a fine silver tube soldered to the outside of the cannula, which is free at one end, and, by the other, communicates with the belt. To the free end is attached a few inches of elastic tubing, terminating with a stop-cock. When the belt is inflated it is even with the surface of the cannula. Dr. Semon has greatly improved this arrangement by placing the fine tube *within* the cannula. This is a most valuable instrument in preventing blood entering the trachea during severe operations on the larynx, pharynx, or tongue.

SENSORY AFFECTIONS OF THE LARYNX.

The mucous membrane of the larynx may lose its natural sensibility, either as the result of central disease or of mischief affecting the fibres which go to form the superior laryngeal nerves. This condition is chiefly met with in patients recovering from diphtheria, and associated with diphtheritic paralysis. In some cases the sensibility of the epiglottis and vocal cords is so completely lost that the contact of the laryngeal probe with the mucous membrane covering these parts, produces neither sensation nor reflex movement in the larynx. This *anæsthesia* may be incomplete, the patient in these cases feeling the contact of the probe; and it may, moreover, affect one or both sides of the larynx. Difficulty of swallowing, especially liquids, is often experienced; and under these circumstances food may enter the air-passages and set up irritation, and thus produce serious and even fatal pulmonary mischief.

In other and rarer cases the *anæsthesia* is due to bulbar paralysis, which leads to

¹ This instrument consists of two portions—a tracheal cannula, and an ascending stem. The stem is first introduced, and, through its mouth, the cannula. A groove in this allows the introduction of a vibrating reed. Dr. Foulis has improved the original instrument; and Heine has, by means of screw mechanism attached to the reed, permitted its removal to one side when the patient is not speaking—an arrangement which gives the freest supply of air during ordinary respiration.

² *Diseases of Throat and Nose*, vol. i. p. 344.

a fatal termination as surely as the diphtheritic form of disease, in a few weeks, terminates in recovery.

In the *treatment* the greatest care should be taken to prevent food accidentally passing into the larynx. If the loss of sensibility is confined to one side, the patient may possibly be able to swallow when lying on the sound side. If both sides are affected, it will be necessary to feed the patient with the œsophageal tube, or for a time by means of nutrient enemata. The surgeon should bear in mind the possibility of the tube entering the larynx, owing to the lessened sensibility of the parts. To prevent this accident it should be guided as far as possible by the finger; and if there should still be any doubt as to its position, as Mackenzie suggests, the patient should be desired to produce a vocal sound before any food is injected. The daily use of the galvanic current by means of the laryngeal rhœophore, and the administration of tonics, especially iron combined with strychnine, will be the best treatment.

A morbidly increased sensibility of the larynx (*hyperæsthesia*), and in some cases *neuralgia*, may follow attacks of laryngitis. These changes from the healthy sensibility of the larynx may sometimes be traced to hysteria, or to the prolonged use of the voice, whilst the neuralgia seems chiefly to result from cold. In these cases the larynx is abnormally irritable and sensitive, the patient complaining of a dry, pricking, or burning sensation, or at times even believing that some foreign body is lodged in the throat. These symptoms are not dangerous in themselves, although often long persistent.

The *treatment* should be guided by the general condition of the patient. Change of air, if possible, sea bathing, suitable mental occupation, with local astringent applications, are usually in the long run successful. Iodide and bromide of potassium have each been advocated, and, in those cases in which rheumatism is suspected, with undoubted benefit.

MOTOR AFFECTIONS OF LARYNX.

Laryngeal paralysis may result from disease of the nervous system, or may be less commonly due to some local change in the muscles of the part. Hence it is either *neuropathic* or *myopathic*. In diagnosing these conditions it is necessary to exclude those cases in which muscular movement is impeded or arrested simply from mechanical causes, such for example as a swollen condition of the inter-arytenoid fold or ankylosis of the crico-arytenoid articulations.

Neuropathic Paralysis.

When the paralysis arises from disease of the nervous system (when it is neuropathic) the cause may be traced either to central disease involving the motor nucleus of the pneumogastric in the floor of the fourth ventricle, or the trunk of the nerve itself; or its laryngeal branches on one or both sides may be implicated.

When disease affects the motor nucleus of the pneumogastric, the laryngeal symptoms are sooner or later associated with others which clearly point to central mischief. The muscles of the soft palate, tongue, or face are commonly involved, and in addition there may be hemiplegia. A certain number only of the fibres which go to form the nerve may be affected; sometimes those which ultimately form the recurrent nerve, or even those fibres which supply a single muscle, may alone be involved.

The laryngeal symptoms vary in a corresponding degree. Hence all the muscles on one side may be paralysed, or only the abductor or adductor. The voice is commonly affected, and if both abductors be paralysed there is marked stridor during inspiration; but these symptoms will be considered more fully in discussing the paralysis due to injury or disease of the laryngeal nerves.

When the whole trunk of the nerve is affected, the laryngeal symptoms vary according to the seat of the disease. Thus, for example, if a tumour involves the entire trunk of the nerve at its exit from the cranium, both the superior and the recurrent laryngeal branches will be implicated, and there will be complete paralysis of the muscles of this side. If, on the other hand, destruction of the functions of the nerve takes place below the origin of the superior laryngeal, then only those

muscles supplied by it will be affected, the depressors of the epiglottis and the crico-thyroid muscle escaping.

If, again, certain motor fibres in the trunk of the nerve remain uninjured, the muscles to which these are destined will of course retain their function. It appears, therefore, that the lesions involving the trunk of the pneumogastric produce a series of laryngeal symptoms almost identical with those which result from disease of its superior or recurrent branch. The functions of the nerve may be wholly or partially destroyed, as the result of pressure from tumour, or the sac of an aneurism, enlarged or suppurating glands, or bronchocele. It might, moreover, be injured during operations on the neck, or during ligature of the carotid artery.

The *superior laryngeal* nerve, as already stated, is occasionally affected as the result of diphtheria. More rarely the paralysis is due to other causes, such as pressure resulting from enlarged cervical glands, or direct injury to the nerve itself.

In these cases motor paralysis is superadded to anesthesia; the depressors of the epiglottis and the crico-thyroid muscle are involved. The epiglottis, therefore, is not properly depressed during deglutition, and food easily enters the larynx. Paralysis of the crico-thyroid muscle may usually be detected by placing the finger over the muscle, and noting the absence of contraction during attempted phonation.

When both sides are affected, the vocal cords are relaxed and have a wavy outline. A slight flapping of the central and most relaxed portion of the cord has been noticed during respiration; where one muscle only is affected, the vocal cord on that side 'remains on a higher level than its fellow.' The voice is commonly lost in these cases. The chief danger seems to result from food passing through the glottis and setting up pulmonary mischief. When, however, one side alone is affected the danger from this cause is much lessened.

The *treatment* must be carried out with the utmost care in order to prevent particles of food reaching the air-passages. The patient must be fed with the œsophageal tube. Galvanism should be used, and tonics combined with strychnia administered. If any local cause can be detected, the possibility of its removal should at once be considered.

The *recurrent laryngeal* nerve may be affected on one or both sides. Complete bilateral paralysis is, however, uncommon; it has been already seen that this condition may be the result of central disease in the medulla, or that it may be due to compression of the trunk of the pneumogastric itself. The recurrent nerves alone are, however, occasionally involved in a cancerous growth of the œsophagus or elsewhere, or they may be compressed by an enlarged thyroid gland or the sac of an aneurism. The symptoms, in whatever manner they may be produced, are by no means uniform; and this variation appears to result from the paralysis being in many cases incomplete, owing to the escape of certain fibres which are thus able to perform their motor functions.

FIG. 157.—Paralysis of Left Recurrent Nerve. (Mackenzie.)

If the entire trunk is involved on both sides, the vocal cords remain passive and immovable in what has been well termed 'the cadaveric position;' midway, that is, between the position of phonation and that of deep inspiration.

There is no dyspnoea but, the muscles of the larynx acting no longer as a barrier to regulate the passage of air from the chest, the patient can neither expectorate nor use his voice properly, and all his attempts are accompanied by great efforts owing to the waste of expired air.

In incomplete paralysis the abductors are most commonly affected, and this appears to be the case whether the paralysis is on one or both sides. Several ingenious explanations have been given to account for this curious fact, but none are entirely satisfactory. If, then, the abductors alone are affected, the adductors acting without their opposing muscles, the vocal cords remain near the middle line; and if, on the other hand, the adductors be affected, the glottis remains widely open. The condition of the voice depends to a large extent on the implication of the tensors

(crico-thyroid and thyro-arytenoid). When the abductors are alone affected dyspnoea is commonly present.

If the paralysis is complete on one side and incomplete on the other, the voice, although greatly modified, is not entirely lost. After a time the affected muscle becomes atrophied.

The danger in these cases depends to a great extent on the seat and the cause of the mischief, but the laryngeal complications are sometimes so severe as to necessitate tracheotomy. In the treatment, therefore, the remedies must be selected according to the exigencies of each case. When the paralysis is unilateral it is commonly on the left side; the left recurrent, from its long course around the arch of the aorta, being especially liable to pressure from aneurismal and mediastinal tumours. The right nerve, however, as is well known, comes into close relation with the apex of the right lung, and therefore may be affected by disease occurring at the apex of this lung.

If the paralysis be complete, the cord on the affected side remains in the cadaveric position, the healthy cord moving towards it and even passing beyond its normal limit. In cases of one-sided paralysis, the voice is usually much altered and some times even lost, and speech is effected when possible with much greater effort than before. There is often considerable stridor, due apparently to the adducted position of the cord.

The prognosis must depend on the cause of the paralysis and the amount of dyspnoea. In the treatment tracheotomy may be required.

Myopathic Paralysis.

The term Myopathic Paralysis may be applied to those cases in which, as far as can be ascertained, there is neither nerve lesion nor any mechanical cause to which the arrested movements can be attributed. What the exact changes are, and whether they lead to subsequent disease in the nervous system, it is not necessary here to discuss, but undoubtedly fatty degeneration and atrophy of the muscular fibres have been observed after death. It is probable, however, that many so-called myopathic cases may be in reality those of true paralysis which have not been recognised as such during life, or even after death in the post-mortem room.

The *abductor muscles* seem to be those chiefly affected; male adults being most liable to this disease. Long-continued use of the voice, exposure to cold, injuries resulting from swallowing liquids too hot or too cold, the irritation set up by the passage of a bone or other hard substances along the lower part of the pharynx—each and all have been regarded as the cause of this form of paralysis. It will be readily seen how liable these muscles are to injuries from such causes, lying as they do between the thin mucous membrane and the posterior surface of the resisting cricoid cartilage, and forming the anterior wall of the canal just at its narrowest and least distensible part.

The *symptoms* are usually well marked; expiration is easy, inspiration difficult, producing stridor and often great dyspnoea. The adductors still retaining their power, the rima glottidis is much contracted and remains so during inspiration. The voice is usually somewhat husky. The only conditions with which these cases are likely to be confounded are those of spasm of the adductors; but the temporary and paroxysmal nature of this affection, and its disappearance during sleep or under chloroform, will as a rule be sufficient to separate the two conditions.

In the *treatment* the impeded respiration indicates tracheotomy as the only method likely to give immediate relief. If syphilis is suspected, specific remedies should of course be administered. Galvanism may also be employed.

Paralysis of one *abductor* may occur with corresponding modifications of the symptoms.

Both *adductors* may occasionally be affected, producing loss of voice. This is especially liable to occur in young women, and in them it may commonly be traced

to hysteria. In such constitutions simple laryngitis or even slight congestion of the throat are very likely to be followed by aphonia.¹

The laryngoscope shows that in attempted phonation the vocal cords are not properly approximated. Although these patients cannot speak by a voluntary effort, yet sound is produced in the reflex act of coughing or sneezing.

A cure can usually be brought about; but it is of the first importance to remove as early as possible any remaining inflammation or congestion, otherwise the aphonia may continue for a very long period. Pigments of iron and of nitrate of silver, or tannin and glycerine, are amongst the most useful astringents, and one of these should be applied daily with the laryngeal brush. The application should not under ordinary circumstances be suddenly omitted, but should be used at longer and longer intervals as the case progresses.

Electricity is also of great value in many cases when the local symptoms have been removed; for it not only restores the voice at the time, but has an excellent moral effect over patients who believe they cannot speak. One *abductor* only is occasionally at fault.

IMPAIRMENT OR ARREST OF MUSCULAR MOVEMENT FROM MECHANICAL CAUSES.

It is unnecessary here to do more than mention the likelihood of tumours in the situation of the glottis interfering with muscular movement. The swelling and thickening of the inter-arytenoid fold, in like manner as the result of syphilitic or tubercular disease, is so obvious that any impairment of movement under these conditions would at once be attributed to its proper cause. But there are cases hitherto scarcely well understood in which the arrest of movement is due to disease affecting the crico arytenoid articulation itself. Dr. Felix Semon² has especially called the attention of the profession to this often obscure and hitherto neglected cause. He regards every form of stiffness of the crico arytenoid articulation which is produced by mechanical causes, as an ankylosis of this joint, and distinguishes two forms—namely, first, the true ankylosis, in which the stiffness is produced by intra-capsular disease; and, secondly, the spurious or false ankylosis, in which extra-capsular changes lead mechanically to impairment of the functions of the joint. In some cases true ankylosis is a consequence of a long-existing spurious one. Luxation of the crico arytenoid articulation means a displacement of the arytenoid cartilage from the articular surface of the cricoid; in some cases both ankylosis and luxation are present at the same time together.³

The joint may be fixed in any position into which it can be naturally moved, or, as a result of cicatricial contraction, it may be drawn across the median line. The ankylosis may be either unilateral or bilateral, but it is not in the latter case necessarily symmetrical. Tumefaction is often, though not always, present; and in true ankylosis may be entirely absent. Again, it may be complete or incomplete, or accompanied with luxation, or this alone may be present.

Dyspnœa is a very constant symptom. The voice may be normal; but it is more likely to be affected, and in some cases is entirely lost. The diagnosis during life is often extremely difficult, and on this head Dr. Semon writes:—‘The diseases with which ankylosis and luxation of the arytenoid cartilages may be most easily confounded are of course, above all others, nervous and myopathic affections of the larynx. There is no doubt that nervous paralysis is the most frequent cause of motor impairments in the larynx; and I wish to say distinctly that always in the first place, unless there are such decisive symptoms as tumefaction and luxation, we must think of a nervous paralysis, if we observe laryngoscopically a motor impairment. If, however, a careful consideration of the case, and a close physical examination of the patient, fail to give us any clue as to the existence of any such nervous

¹ This form of paralysis has been also attributed to rheumatism and over-use of the voice both in speaking and singing.

² *Medical Times and Gazette*, vol. ii. 1880.

disorder, we shall, especially if there is a history of one of those diseases enumerated¹ preceding the laryngeal trouble, have to think of the possibility of an anchylosis of this articulation. Very unusual position of the immobile arytenoid cartilages and corresponding vocal cord; absolute immobility; signs of previous ulcerative diseases; abnormal distortion of the mucous folds; and, above all, tumefaction at the basis of the immovable arytenoid cartilage, will, of course, much foster such an idea. The possibility of a combination of nervous and mechanical impairment must not be overlooked, and, in such a case, the question is which has been the primary one. Typhoid fever, syphilis, or diphtheria, for instance, may lead to nervous paralysis or to anchylosis as a result of ulceration; and, on the other hand, the anchylosis may supervene on the paralysis, &c.²

Treatment.—It may be necessary to dilate² the stricture, or first to perform the tracheotomy in those cases in which respiration is seriously interfered with. It is of course desirable, when possible, to endeavour to prevent the anchylosis, and this is best accomplished by rest of the parts.

Spasm of the Glottis.

Spasm of the glottis is especially liable to attack children during their first dentition, and is often in severe cases associated with spasmodic contraction of some of the muscles of respiration. The diaphragm and intercostal muscles are very commonly affected. It also occurs in the adult, women being more liable to these attacks than men. As already stated, it may be the result of direct laryngeal irritation, but it is often a purely nervous affection.

In *children* the disease is not common. By far the larger number of cases occur amongst male children during the first two years of infant life between the ages of six and eighteen months. It is said that children of the poor are much more liable to be affected than those of the rich, but certainly cases are found amongst the wealthier classes. It seems to be most frequent amongst scrofulous children and those who are the subject of rickets. Dr. Gee,³ who has paid much attention to this disease, believes that season has a marked influence in the production of the disease, having observed most of his cases during the first six months of the year. Children during winter and early spring are often cooped up in unhealthy dwellings, and one of the results of this appears in a condition of the nervous system especially prone to laryngeal spasm. It has been pointed out that the attack often comes on at the time of weaning, being perhaps in many cases induced by the improper use of farinaceous and indigestible food. Amongst the exciting causes should be mentioned teething, and the irritation produced by improper food. An attack sometimes comes on apparently from the simple act of sucking, and crying occasionally has the same effect.

The *symptoms* are usually unmistakable; they are sudden in their onset, and may take place without warning. On inquiry, however, it will often be found that the child has been ailing for some days. The fit often takes place at night; it is marked by a series of short, stridulous inspirations with increasing intervals, accompanied by great dyspnoea; then the glottis is spasmodically closed, and for a time respiration ceases. In this condition the child may die presenting all the symptoms of asphyxia. More commonly, however, the spasm passes off, air again enters the windpipe, and the little patient recovers from the storm of spasm which has affected both the glottis and the diaphragm, and the danger for the time is over. In severe cases some of the muscles of the hands and feet are affected during the fit. The least cause often produces another paroxysm, or it may not occur again; but there is great variety in the severity and frequency of the attacks.

Treatment.—During the attack the child should be raised, and cold water should be dashed upon the chest and face. At the same time, if it be possible, it should be placed in a warm bath. Chloroform is a very valuable remedy in cutting short the

¹ Typhoid fever, Variola, Syphilis, Diphtheria, Phthisis, and Gout.

² Schroetter's hollow bougies are recommended for this purpose.

³ *St. Bartholomew's Hospital Reports*, vol. iii. p. 104

spasm, but it must be administered with great care and under proper supervision. After the fit is over, it is important to clear the intestinal canal of any possible source of irritation; for this purpose grey powder alone or mixed with rhubarb is useful. Musk has been successfully used by Dr. Mackenzie. He suggests the following formula: Moschi gr. jss., Sacch. Alb. gr. ij., Pulv. Acaciæ gr. ij., Syrupi Aurantii Flor. m xx., Aquæ ad ʒj. Chloral, if the fit occurs at night, is a valuable remedy.

In the after treatment bromide of potassium has been highly recommended. It is important to attend to the gums, especially if there is any possibility of a tooth being the cause of the irritation. The diet should be most carefully regulated. Farinaceous or other food likely to disagree should on no account be permitted. The clothing of the child should be warm and light, and it should, when possible, be placed in a well-ventilated apartment.

In *adults*, women are more liable to be affected than men. The disease has commonly been attributed to hysteria, and sometimes takes place in phthisical patients, or may happen apart from any discernible cause. The attack closely resembles the laryngismus of children, but is very rarely if ever fatal if we exclude those cases which have their origin in some organic mischief. The laryngeal appearances beyond those due to the spasm are not marked. The part may appear indeed quite normal; but more commonly there is slight congestion.

ARTHUR E. DURHAM, 1870.

ARTHUR HESSMAN, 1882.

DISEASES OF THE INTESTINES.

ABDOMINAL ABSCESSSES.

AN abscess which originates in the anterior abdominal wall, in the sub-peritoneal cellular tissue, in the region of the loins, or in the pelvis, and is totally unconnected with disease of bone, or with ulceration of the bowels, is not a very common occurrence; but we occasionally meet with such a case, and it is requisite to consider its peculiarities and treatment.

An abscess originating in the substance of the muscular parietes is most frequently the result of a bruise, and may be treated as abscess in any other position. But one commencing in the cellular tissue of the loin, or iliac region, is generally obscure in the commencement; frequently produces much constitutional disturbance in its progress; and is very often fatal in its results. Abscesses which occur in these situations are sometimes slow in formation; but in some instances increase with great rapidity, and if not opened early may acquire a large size within a week or ten days. According to the rapidity of their progress will be the acuteness of the symptoms which accompany them. They occur in children as well as in adults. When situated in the pelvic region they may be mistaken for psoas abscess dependent on diseased vertebrae; or some kind of tumour growing in the cavity of the abdomen, or, in children, from the resistance of the abdominal and psoas muscles and the drawing up of the thigh on the belly, commencing disease of the hip joint might even be suspected, if the conditions be not particularly examined into.

A very sickly child was admitted into the Hospital for Sick Children, under the care of Sir W. Jenner, with a large prominent roundish swelling on the left side, between the region of the kidney and Poupart's ligament. There was very little indication of pus, or fluid, in the swelling; its shape and consistence conveyed the impression that it might be a malignant growth. As some doubt existed as to its character, a fine trocar was passed into it by the writer, and some thick pus immediately escaped through the cannula. A small opening was then made through the parietes into the abscess, which allowed the free escape of pus. The child very shortly recovered. A child was admitted into St. George's Hospital with much swelling, and great tenderness about the left iliac fossa: the thigh was bent on the body, and kept drawn up; any attempt to extend it was attended by great pain; so much so, that it was impossible, on account of the struggling and crying of the child, to make out the extent or the seat of the mischief. Chloroform was therefore administered; under its influence the thigh was readily extended, and the mischief found to be confined to the iliac fossa. Here was a swelling of some extent, and all the tissues over it thickened and hardened; the skin was darker coloured and more red than natural. Though fluctuation could not be detected, a small incision was made over the most prominent point, and cautiously extended to some depth; but, as no pus escaped, exploration was not carried further, and a poultice was ordered to be applied. On the second day, a sudden flow of pus took place through the wound, relief to all the urgent symptoms followed; and the child recovered shortly.

Acute and large abscesses occur in the sub-peritoneal cellular tissue about the region of the ovaries after the period of child-birth. For an account of them, and their treatment, we must refer the reader to Vol. I. pp. 107, 108.

Abscess of the abdominal region is often connected with an aperture the result of ulceration of the alimentary canal, either of stomach or intestine. Such an abscess may arise from perforation of the bowel, the result of simple ulceration; or the lodgment of any foreign body in the intestine; often from ulceration set up in the gall-bladder by a gall-stone; or from stricture of the intestine; and not unfrequently from some cancerous disease of the alimentary tube.

When such an abscess occurs, its contents will generally consist of pus mixed

with *fæces*; but occasionally the opening in the bowel may be so small, that very little of its contents have escaped; sufficient, however, to set up the secondary mischief. When such an abscess is opened, the escape of mere pus alone does not justify an opinion that the bowel neither is, nor has been, implicated. It will happen occasionally, some days after clear pus has been discharged from the opening, that *fæculent* matter is observed for the first time to be mixed with the discharge. The contraction of the walls of the abscess may probably disturb some of the former attachments of the intestine, and thus facilitate the renewal of an escape of its contents. The discharge in most cases, especially at first, is most offensive.

Abscesses connected with the bowel cannot be said to follow any definite rule, either as to symptoms, rate of progress, or termination. They may be obscure in their commencement, and in their progress, or marked by violent pain; while the medical attendant may be daily watching for an opportunity to give exit to pus at some favourable point, the swelling may suddenly subside, and disappear by evacuating the contents, through some fresh opening, into the bowel, the pus being discharged *per anum*.

When of an acute character, the symptoms of a '*facal abscess*' are very marked. Sudden pain is referred to the part affected, often of a very severe character; constipation is often the forerunner of the attack, or accompanies it. The pulse and tongue sympathise early in the mischief; the former becomes rapid; the latter loaded and creamy, and soon dry and brown. There is often great anxiety and restlessness; much thirst, and a hot dry skin. There is very frequently, early in the attack, distinct fullness of the part implicated; and, in addition to extreme tenderness and an intolerance of pressure, general indications of diffused peritoneal inflammation. The most frequent seat of such abscesses is the region of the *ileo-cæcal valve*—the right iliac fossa, but they may occur in any part of the abdomen.

Sometimes the formation of pus is so rapid, and the mischief in the peritoneal cavity is so general, that the patient dies within a few days of the first symptom of pain. Mr. —, late House-Surgeon of St. George's Hospital, while walking in Hyde Park, was suddenly seized with excruciating pain about the right iliac fossa. Though but a very short distance from his lodgings, he was obliged to be carried home. When seen by the author in the evening, there was intense pain in the right iliac region, with a certain amount of fullness, and great tenderness on pressure. The skin was hot; the pulse rapid, and there was great anxiety of countenance. The symptoms were in no way relieved by the treatment prescribed in consultation with the late Dr. Bright. The case proved fatal in a few days. On examination after death, a large abscess was found to occupy the right iliac fossa; the boundaries were formed by adhesions of the intestines and the parietal peritonæum. The contents were pus and feces. The appendix *cæci* was found ulcerated through at its extremity. No solid substance could be found, to account by its pressure for the ulceration.

This perforation was probably the result of ulceration of the bowel commencing in the mucous membrane, and subsequently making its way through the muscular and peritoneal coats, such as is often known to occur in the later stages of enteric fever. The author has seen other cases in which death has followed even more rapidly; sudden collapse with acute pain in the lower parts of the abdomen, with all the symptoms of acute peritonitis, followed by death in two or three days.

It is desirable to note that when abscess is the result of an ulcer perforating the wall of the cæcum, much will depend on the exact seat of that ulcer; viz. whether it be in the part covered by peritonæum, or on the posterior surface where the intestinal wall is in contact with cellular tissue. In the former instance, perforation is rapidly fatal as the immediate cause of acute peritonitis: or adhesions of the opposed peritoneal surfaces may have occurred prior to the perforation, and the abscess become limited by such adhesions, and after a time present externally; the patient then has more chance of recovery after the evacuation of the pus. In the other instance, in which an abscess is the result of perforation of the posterior wall of the intestine, and the escape of *facal* matter into the cellular tissue, the abscess is less apt to be limited; and matter often burrows in a variety of directions.

A woman admitted to St. George's Hospital, under the author's care, had extensive suppuration and numerous sinuses with various openings in the right groin and on the outer surface of the right ilium. These were freely laid open, but she gradually sank exhausted. On examination after death, a circular smooth-edged small opening was found in the wall of the

posterior surface of the cæcum, communicating with a large abscess in the right iliac fossa, with numerous sinuses running in various directions. The ulceration appeared to be due to an attack of fever.

In a patient, a lady under the care of the author, an abscess which had apparently commenced in the cellular tissue of the pelvis opened into the rectum, bladder and vagina: and in another case openings existed between the abscess, bowel and vagina. In both instances recovery took place after free incision, so as to allow of ready escape of pus. Some time elapsed before the various openings closed, yet ultimately all healed, and left no trouble behind.

Occasionally an abscess in this neighbourhood is much more tardy in its progress; and although matter continues to collect, the patient, having passed over the first acute stage of the attack, may soon improve in health and appetite; the general tenderness of the abdomen, or distension of the bowels—should either have existed—commences to subside; and a local swelling remains in some portion of the abdomen, marked by external fulness, and often by a well-defined surrounding wall. The skin over this part becomes more red and shining than that of the immediate neighbouring surface; then darkens in colour, and becomes thinner at one or more spots; and either ulcerates or is punctured, when pus readily escapes.

It is safe and judicious treatment to open such an abscess, as soon as it may be suspected to have formed, and to be within reach of the knife. If the incision be delayed until matter makes its approach towards the surface, it will generally happen, during this process towards self-liberation, that the pus works its way in several directions; it has been so long kept back by the resisting action of the abdominal muscles and fasciæ, that it has burrowed wide and deep: so when the external opening has been long postponed, by nature or the surgeon, we find, in addition to the suppurating cavity in the iliac region, that the abscess has passed under Poupart's ligament and among the abductor muscles of the thigh, or deep into the pelvis, and may present itself in the perinæum or have opened into the rectum or vagina. Abscess in the left iliac fossa, independent of cancer, is more rare, but the author has lately had under his observation a case in which an abscess appeared to have commenced a little above Poupart's ligament in the left inguinal region, from some cause not readily determined, and this gave rise to perforation of the sigmoid flexure, followed by an external fecal fistula. We can never define what bed these abscesses may form for themselves, or how, when, or where they will discharge their contents. If one be opened late in the progress of the case, long sinuses will often be found, which lead from the opening in the abdominal wall to the surrounding parts, and thus render the ready escape of matter difficult. Under such circumstances, after a time, other collections of matter point, either in the groin, in the thigh, or about the ischiatic rami. Many a patient will, however, sink soon after the opening of a fecal abscess; not only has he to contend against the effects of profuse discharge, but he has also the extra evil of a too early and free escape of intestinal contents from the artificial aperture.

Notwithstanding the severity of such cases in their general aspect, and the frequently fatal results they entail, we occasionally find a patient gradually recovers after he has endured the opening of a great number of consecutive abscesses; the sinuses slowly contract; the discharge diminishes by degrees, and ultimately ceases; and the orifices of the abscess cicatrise one by one. The patient probably recovers only with a crippled limb. The suppurative action usually damages the psoas and iliacus, and often the adductor muscles to such an extent, that the movements of the thigh are subsequently restricted, sufficiently to prevent the limb being extended to its natural limit.

The general treatment of this class of cases is not to be laid down as simple, nor conveyed in a few words. It depends entirely on the course of the case.

In the early stage, *i.e.* of pain, constipation, and fever, constitutional measures and local treatment must be combined. Opium internally, and hot fomentations, perhaps leeches, externally, are usually most beneficial at first. Opium may be given in full doses, and often repeated. It may occasionally be considered requisite to combine with it small doses of calomel, but this should be prescribed with much caution. Purgatives, as a rule, should be strictly avoided. Under the influence of opium alone the bowels will act as early as their condition will permit; and quite soon

enough to answer nature's purpose, *if they will act at all*, without the aid of purgatives.

When the patient survives the shock of the attack of inflammation, so soon as matter is suspected, the part should be explored, and, if possible, the pus let free. Under the influence of an anæsthetic alone, can a satisfactory examination be made, in a case such as we are now considering; and we would under all conditions which indicate, though they do not absolutely prove, the presence of pus, urge the use of ether or other anæsthetic, that a thorough examination may be instituted, and exploration made if deemed advisable.

Great attention and care in treatment are necessary, as soon as the pus has an outlet, with strict cleanliness to prevent excoriation from the discharge, and also to avoid bed-sores. As the discharge is usually extremely offensive, the chamber may become insufferable, if not constantly and carefully ventilated. A free use of disinfectants is requisite in the room, as well as in the local dressings. A constant and liberal supply of nutritious food and stimulants are necessary to meet the wasting and lowering effects of profuse secretion from the abscess-walls. It is often surprising how much wine patients require, and will take with advantage under these conditions. The bowels must be carefully watched; they are often apt to become relaxed, and diarrhœa, if unchecked, may soon carry off the patient. If collections of matter should point in other parts, they ought at once to be let out; or if superficial sinuses lead from one abscess to another, they should be laid open.

The usual conditions found after death, in cases of fecal abscess, are general adhesions of the intestines and viscera in the immediate neighbourhood; some portions of which may form the boundaries of the abscess-wall. The communication with the intestine is generally very clear; often several may be observed; but when more than one exists, the greater number are commonly the result of ulceration *from* the abscess *into* the gut.

Most commonly the mischief which produces fecal abscess, independent of cancer, arises near the ileo-cæcal valve; ulceration of the appendix is one of the most frequent causes.

In the 'Transactions of the Pathological Society' (vol. vii. p. 210) is recorded a case in which perforation of the cæcal appendix was occasioned by the impaction in it of an intestinal concretion. Another case is detailed (vol. xii. p. 85), in which a fistulous orifice in the abdominal parietes opened into a circumscribed cavity, which communicated with the interior of the colon and duodenum, and indirectly with the gall-bladder. This was probably the result of a gall-stone ulcerating into the duodenum, and accidental rupture of the colon.

Fæcal abscesses and fecal fistulæ occur in other parts of the abdominal wall; they are most frequently connected with the large intestine, and are generally the result of some cancerous obstruction attended by ulceration of the bowel above, which, extending to the integuments, allows a partial escape of feces.

A case of fecal abscess and fistulæ communicating with the cæcum, caused by cancerous disease of the large intestine, is recorded in the 'Transactions of the Pathological Society,' vol. i. p. 205; another, of abscess in the abdominal walls in connection with cancer of the stomach, vol. xi. p. 122; and a third, of fistulous openings through the abdominal parietes communicating with the transverse colon and stomach, the result of cancerous disease, vol. viii. p. 221.

The treatment of fecal fistulæ dependent on cancer does not call for much remark.

The patients often linger much longer than might be expected, provided they can take plenty of nourishment; but they often succumb much more rapidly than is anticipated by those in attendance; it is therefore best to warn the relatives of the sufferer of the possibility of sudden collapse when such disease exists.

INTESTINAL OBSTRUCTIONS.

The causes of intestinal obstruction are various; its occurrence is fraught with much danger, but too often the forerunner of death; its symptoms are severe and distressing; its diagnosis is too frequently obscure; and its treatment uncertain, and often unsuccessful; the consideration, therefore, of such an important subject as the

pathology and the symptoms of intestinal obstructions, and the measures to be employed for their relief, is one of very great importance, and demands most careful investigation.

In entering upon an inquiry beset with so many difficulties, it has appeared to us a very important point, at the outset, to endeavour to classify the causes of obstruction, so that, in some measure, we may be able to determine, according to the symptoms, whether the obstruction depends on an acute strangulation entailing great and imminent danger to life; or on a slowly altered condition of the intestine itself, or of the adjacent tissues. Under the first condition the treatment must be decided; and to prove effective, must be early applied. In the second, there is generally more time to consider the prospects of life, and the advantages of interference. In the first, without prompt and entire relief, death generally follows rapidly in the wake of the onset of the symptoms. In the second, while we are calculating our measures, the symptoms may even subside; and their sudden cessation be followed by perfect recovery.

We therefore propose to divide the causes of obstruction into—first, those we may term sudden; such as are productive of acute and rapidly fatal results, if not presently relieved; and, secondly, those more slowly acting; productive of symptoms, chronic when compared with the first; and such as sometimes subside with the aid of medicine alone, or even occasionally without it.

Those which generally produce most acute symptoms, early in their attack, sudden in their nature, and, if not relieved rapidly, fatal in their results, comprise,

1. Congenital strictures or malformations.
2. Foreign bodies impacted in the intestines, and introduced through the stomach; originating in the gut from particles of indigestible food, &c., or escaping by ulceration from the gall-bladder.
3. Twisting or 'dislocation' of the bowel—most frequently observed in the large, but often in the small, intestine.
4. Loops, formed by bands of false membrane, adherent at both extremities; by diverticula, adherent by their apices to some portion of the viscera or abdominal wall; or by the fimbriated processes or other portions of the viscera contracting adhesions, so as to form rings or apertures for intestine to become entangled in—all these usually the result of peritoneal inflammation.
5. Mesenteric pouches, foramen of Winslow, or 'thickened peritoneal sheaths,'¹ the result of old herniae.
6. Invagination, often caused by worms, intestinal polypi, &c.

It is hardly necessary to mention that all forms of external hernia are excluded in this consideration.

The more slowly acting processes productive of obstruction, in which the symptoms are at first not urgent, and in which relief sometimes occurs without assistance, are—

1. Constipation, habitual or accidental.
2. Inflamed thickened intestine, the result of injury.
3. Chronic peritonitis (tubercular) and abscess.
4. Tumours pressing on the bowel—hydatids, &c.
5. Simple stricture of intestine, the result of ulceration and other causes.
6. Cancer of the bowel, producing contraction of the gut.

Although we have divided the usual causes of obstruction into two classes, each productive of its peculiar train of symptoms and effects, one of the acute character, the other of a chronic nature, yet it must be clearly understood, for it will certainly be found so in practice, that this division must only be taken as a mere outline map of the difficult country we have to explore; that in many cases the symptoms may subside from the acute into the chronic, or from a quiet state become very severe. It must not be taken as a fact in every case, that acute symptoms cannot or do not depend on any one of the latter causes of obstruction; or a more chronic state of symptoms on any of the conditions noted in the first division; but, as a general rule,

¹ Rokitsansky's *Pathological Anatomy*, vol. ii. p. 59.

we may venture with some degree of assurance to assert, that the several symptoms which will mark the cases coming under our first division are urgent, acute, and rapidly result in collapse and death, if not relieved by nature or art; while the greater number comprised in the second division are attended by symptoms which come on by degrees, may last many days, often weeks, or even months in some cases; are generally by so much the less urgent than the former in character, and permit of delay in treatment as regards surgical interference, allow time for consultation, are often capable of medical relief, and, if surgical treatment be considered requisite, offer many more features favourable towards the prolongation of life, than do the acute cases of obstruction. It must be borne in mind that constipation, or entire stoppage of defæcation, is not an absolutely requisite symptom to indicate fatal obstruction of the intestine; nor, in suspected organic obstruction, should we presume to say that the disease has yielded to our treatment, even though a diarrhæal action occurs; it will probably last but for a short time, or the quantity of fluid passed will be small in proportion to the frequency of the motions. A relaxed state of the bowels in stricture is usually indicative of ulceration, and may occur, in old contracted stricture of the intestine, within a very short period of death.

Before entering upon the consideration of the individual causes of obstruction, it appears desirable (1) to attempt some kind of estimate of the periods of life at which different kinds of obstruction may occur; (2) to review generally the respective symptoms dependent on the various organic or accidental conditions; (3) to determine under what circumstances, and with what hope of success, operative interference may be had recourse to.

As regards our first proposition, it may be laid down, generally, that the causes of obstruction vary somewhat in youth, middle age, and old age. In youth they appear to be due chiefly to internal strangulation, caused by bands of lymph, adherent omentum, or diverticula, adhesions of various coils of bowel to each other, intussusception, foreign bodies taken by the mouth, cancer rarely, and that usually in the rectum. In middle life, from twists of large or small intestines, pressure caused by tumours, or pedicles of ovarian or other growths, gall-stones, intestinal concretions and foreign bodies, intussusception, simple or syphilitic stricture, mesenteric hernia, intestinal strangulation by bands, &c.; peritonitis, often resulting in abscess, simple constipation, and from cancer. In advanced life from cancer, thickened intestine, the result of an old hernia or other accidental cause, intussusception, simple or accidental stricture, and lastly from twist or internal strangulation.

The following table indicates to some extent the relative frequency of different causes of obstruction, irrespective of age. It is copied from Mr. Hinton's valuable communication on intestinal obstructions.¹ In 135 cases, the following were the causes of obstruction, in the order of their frequency:—

Diseased uterus	1	In first column	19
Stricture of ileum	1	Concretions, calculi, foreign bodies	7
Cancer of small intestine	2	Doubtful	8
Internal hernia:		Peritoneal adhesions, tubercles, &c.	9
Inguinal, high up	1	Stricture of sigmoid flexure	10
Diaphragmatic	2	Ditto colon	11
Meso-colic	2	Ditto rectum	11

1. Congenital malformations of the intestinal canal, giving rise to immediate obstruction, are almost entirely confined to the rectum and its external aperture. These deformities, and their treatment, will be found described in the essay on the SURGERY OF CHILDHOOD, and therefore require no further notice here.

Another, but very rare, condition of stricture has been occasionally found in the duodenum of infants: the two following cases illustrate these structural alterations:—

¹ *Ass. Med. Journ.* 1853, p. 431.

A child, when born, presented no unusual symptoms for the first twenty-four hours; vomiting then came on, and continued, with short intermissions, until death, which took place some thirty eight hours after birth. The bowels were never relieved during life. The only disease found was a stricture of the duodenum, close to the entrance of the gall-duct; so that a probe passed down the latter entered the duodenum immediately below the constriction. There was nothing to indicate from what cause the constriction had occurred. On the gastric side of the latter, the duodenum was immensely distended; so much so, that at first sight it appeared like the pyloric end of the stomach itself; and only by a more careful examination was the distinction between the stomach and intestine detected, by a ridge running around their place of junction.¹

A child eighteen months old was admitted into the Hospital for Sick Children, under the care of Dr. West, apparently in much pain; constantly whining, restless, and throwing about her legs and arms. The mother had noticed that the child vomited frequently, rejecting everything she took; there was considerable constipation. The child died in a few days. The stomach presented a constriction, beyond which was a pouch which looked at first like the stomach, but ended sharply at a spot where there was a fold of mucous membrane; beyond this followed intestine of ordinary character. A probe inserted into the bile-duct, from without, passed between the two surfaces of this septum, and appeared just below the stricture. The pouch was detected to be duodenum; and what appeared to be a fold of mucous membrane at the further end of the pouch, proved to be a septum stretched with a slight obliquity, across the calibre of the bowel. The septum was perforated almost exactly in the middle, by a small hole nearly circular, and with a smooth edge. The valve possessed all the ordinary characters of intestinal mucous membrane.²

These strictures, so similar in position and in anatomical relations, were probably the result of an abundantly developed valve of the duodenum; that in the second case becoming more obstructive as the infant grew, on the principle that orifices in membrane or soft tissues, the result of diseased action, generally acquire a tendency to contract towards their centres.

Such cases are interesting, but are quite beyond the reach of treatment.

2. Obstructions, the result of foreign bodies lodged in the intestines, have already been considered in the essay on INJURIES OF THE ABDOMEN; we merely allude to them to complete the causes of obstruction in our table.

3. Twisting, 'dislocation,' or displacement of intestine, producing obstruction to the passage of its contents, is not a very common accident, but demands very careful examination when it occurs: for not only is its origin peculiar and its symptoms often obscure, but its treatment is a matter of very great consideration.

'Incarceration may be the consequence of a rotatory movement, and of this there are three varieties.

'a. A portion of intestine may have become twisted upon its own axis; and we then find that even semi-rotation causes such an approximation of its parietes, that they touch, and close up the passage. This can probably only occur in the colon; and according to cases on record, only in the colon ascendens. Accumulation of gas, and unequal filling of different portions of the intestine, appear, as far as we are able to judge from the few cases which have been noticed, to be the cause. Such an occurrence is scarcely conceivable in the small intestine, on account of the uniformity of its calibre, the absence of angular flexions, and its loose position, as every rotation of one portion upon its axis would be counterbalanced by the rotation of the next segment.

'b. The mesentery may be the axis, and the intestine will then be rolled up upon the former; i.e. the entire mesentery, or a portion of it, is twisted into a cone; and in proportion to the number of its rotations, more or less of the intestine will be dragged after it. In this case, we must take into consideration the traction and the pressure which the dependent mesenteric cone forms with the base whence its point rises. This variety can scarcely occur anywhere but in the small intestine and its mesentery.

'c. One portion of the intestine, either single or double—a coil—may afford the axis round which another portion with its mesentery is thrown, so as to be through-

¹ *Pathological Trans.* vol. xii. p. 101. From the plate which accompanies the description given by Dr. Wilks, it would appear that the contraction in all probability arose from a highly developed valve of the intestine; in the centre of this valve or stricture may be seen a very small circular hole, apparently not larger than would admit a probe.

² *Ibid.* vol. xii. p. 121.

out in contact with the circumference of the axis, and thus to compress it like a ferule. This variety is 'evidently a higher degree of the first, in which a portion of the intestine is merely compressed from before backwards, and, as it were, flattened down. A coil of small intestine, the sigmoid flexure, or the cæcum ~~may~~ form the axis.

'The last two varieties occur, like the first, chiefly at an advanced period of life. In early life, a predisposition to the affection may be caused by a congenital malformation of the mesentery, by large hernia, or by small hernia when there is adhesion of the intestine.'¹

It is a matter of some importance to be reminded of, that the seat of *most* incarcerations, *and of all twists*, will be found towards the posterior unyielding wall of the abdominal cavity; for it is only in that direction that pressure exerted on the intestine can effect its incarceration; the occurrence of a similar relation anteriorly is inconceivable, on account of the smoothness and yielding nature of the parts.

The symptoms of twisting of the intestine, especially of the sigmoid flexure (which is the most common variety), are very urgent from the first; great pain is suddenly experienced in a small circumscribed spot of the abdomen; obstinate constipation usually setting in from that date. If the sigmoid flexure is implicated, there soon follows very considerable distension of the abdomen often distinctly observed to be chiefly confined to the left side. The distension of the abdomen is generally much greater when the large gut is affected than when the twist implicates the small intestine. In the latter conditions, fluids may be injected into the rectum very readily, and may remain, or return tinged by fecal matter. In twists of the sigmoid flexure, we have injected fluids into this division of the bowel; if retained for a time, they do not return; the fluid has been thrown into the dilated sigmoid portion, and cannot again escape; vomiting is generally present, and often very copious and constant.

The following case illustrate the history and pathological conditions of these accidents:—

A man, aged 28, having suffered for five days from irremediable constipation, died five hours after admission to the Hospital-ship *Dreadnought*. The sigmoid flexure occupied nearly the entire portion of the front of the abdominal cavity, and was in a gangrenous state. The bowel was immensely distended; obliteration of the muscular bands, and rupture of the serous coat, having taken place. This portion of the gut had been originally highly developed, and had now become strangulated, from falling over on itself towards the right side, causing a twisting and strangulation. The patient had, on previous occasions, been subject to constipation.²

A man, aged 65, was admitted into St George's Hospital with a large circumscribed swelling, which occupied the greater part of the abdominal cavity, and apparently extended into the pelvis. Fluctuation could be distinguished over the whole of the tumour, the surface of which appeared smooth. No solid matter could be detected in any part of it. Percussion gave a clear sound in the upper part of the abdomen only, and there but to a small extent. *There was a tendency to diarrhoea.* A day or two after admission, peritonitis came on, with great pain in the abdomen and constant sickness. He died on the fifth day. The greater part of the peritoneal cavity was occupied by a large dark-coloured tumour, which had displaced the various viscera, and encroached upon the chest. This mass was formed of the sigmoid flexure enormously distended. The dilated bowel was connected to the left iliac fossa by a pedicle formed by an exuberant meso-colon, which was twisted upon itself, and had thus occasioned partial obstruction of the gut; the communications respectively leading into the colon above, and the rectum below, being small and tortuous. The sigmoid cavity was distended with fluid fæces, and contained one or two hard masses. The mucous membrane was of a dark livid colour, but not ulcerated. Extensive evidences of peritonitis were present.

A man, aged 55, was admitted into Charing Cross Hospital, nine days after almost complete obstruction of the bowels. A displacement of the bowel implicated the termination of the ileum, cæcum, and ascending colon. The latter was pressed upon and strangulated by the termination of the ileum and its stretched mesentery. Just at the part where the pressure was exerted, a gland in a calcareous state, as large and hard as a marble, lay immediately under the strangulated bowel, and had considerable influence in exaggerating the obstruction, as every effort to force the contents of the gut onwards tended to carry the gland into the opening. Close above the constriction the internal coats were extensively

¹ Rokitsansky, *Pathological Anatomy*, vol. ii. p. 52.

² *Pathological Transactions*, vol. i. p. 103.

ulcerated, and perforation was about to take place. In this case an attempt was made during life to relieve the obstruction by operation in the left loin, but without success, as the obstruction was above the opening made in the bowel.¹

A boy was seized with a violent pain in the stomach, and with sickness. These symptoms continued, varying in intensity, with complete constipation. He died on the ninth day. The intestines were matted together. The duodenum, jejunum, and ileum were greatly distended; the lower part of the small intestine was highly inflamed, and two loops of it were quite black from congestion. The mesentery of these loops had been twisted on itself, and had caused strangulation of the gut attached; and while in this state, the folds had fallen on an intestinal diverticulum proceeding from the small gut to the linea alba, about one inch below the umbilicus, and thus gave rise to an additional amount of mechanical obstruction to the circulation and contents of the bowel.²

These cases are apt illustrations of the usual forms of 'twist' of the bowel, such as occur, (1) in the sigmoid flexure; (2) about the cæcum; (3) of the small intestine. As a rule, such twists, when found in the small bowel, are usually nearer its lower than its upper extremity.

Rokitansky has very justly observed that the *predisposition* towards incarceration from twisting of the gut is dependent on a congenital, or acquired long, loose, flabby mesentery or meso-colon. But the mere existence of such a state, which allows of very free movements of the bowel, is hardly sufficient to account for the occurrence of a sudden strangulation of the parts. It appears to us that something is requisite to establish the twist; and that this something is to be found in an accumulation of feculent matter, invariably present wherever such twists occur. This accumulation of feces, fluid or solid, so loads and distends the bowel, that if accidentally it becomes shifted into a position unfavourable for the free passage of its contents, the intestine has no power to recover itself; nor has its peristaltic action any influence in altering its position, or that of the contained feces. The mischief once started continues to increase by continued inlets of feculent matter, without any corresponding outlet, for it will frequently be seen that, though fluid feces from above can enter the sigmoid flexure when twisted, it rarely happens that much is able to escape into the rectum.

If, in the dead subject, the large intestine be distended artificially with water, and the mesentery of the sigmoid flexure be abundant, this portion of bowel is first seen to bulge forward, and then gradually rise up towards the diaphragm. In this movement there is a slight tendency observed towards a folding of the intestine on its mesentery; this when the abdomen is open, and no restriction applied to the bowel. We have not, however, been able, by simply distending the sigmoid flexure, to produce actual twist; perhaps our experiments were too restricted; and no doubt some other cause is wanting to induce it besides distension and free movement. Something, perhaps, depends on the motions of the body, more, perhaps, on the presence of the other viscera and the pressure or relaxation of the abdominal wall during life. The following particulars of a case bear strongly on this portion of our subject.

A man, aged 45, was attacked on the 10th of November with diarrhœa. This ceased on the 12th. On the 13th he was occasionally sick, and complained of deep pain in the region of the bladder; and this pain became paroxysmal and severe until his death. Along the whole of the left side an unusually hard and broad ridge could be felt, extending from the region of the stomach to the bladder. Death took place on the 15th, almost suddenly.

The peritonæum contained a considerable quantity of bloody serum. In the epigastric region was seen the transverse colon, with the omentum stretched and adherent to the abdominal parietes, on the left of the umbilicus. The left side of the abdominal cavity was entirely occupied by the sigmoid flexure of the colon; it lay obliquely, and had forced the diaphragm high into the chest. The meso-colon, which was greatly thickened and elongated, had become twisted on itself, and the intestine with it. The gut was enormously distended by fluid feces, and was livid, from almost complete strangulation of its coats and vessels at the seat of twist. Mr. Gay, under whose care this case fell, found on examination that, in the state of tension, if the bowel was partly untwisted and then relaxed, it sprang back forcibly to its acquired and altered position; but that this tendency became less as the bowel was gradually emptied of its contents, until it required little manipulation to restore

¹ *Pathological Transactions*, vol. ii. p. 222.

² *Ibid.* vol. vii. p. 205.

the bowel to its natural position, and this without any marked disposition to again become twisted. He very justly remarks, *that usually the tightness of the twist is in proportion to the distension of the bowel.*¹ A tube passed up the rectum after death in this case was with some little trouble introduced into the sigmoid flexure, beyond the obstruction, and could empty the bowel. When this was effected, and the body rolled over on the side, the twisted bowel righted itself.

The facts just quoted point to this rule in treatment, that relief in twist of the sigmoid flexure is just possible without opening the abdomen, provided the long tube can be introduced into the distended gut, its contents drawn off, and the twist reduced by the altered condition of the bowel. But no operation for the ultimate relief of the patient will be successful without the intestine be first unloaded, and the twist subsequently reduced. It may be stated as an axiom in these cases, that once formed, the twist prevents the escape of the contents, and the contents of the twisted portion maintain the distortion; to remedy the latter, the contents must be removed.

It will be observed that in one case already mentioned,² the serous covering of the intestine was found ruptured, after five days of constipation. This rupture had no doubt occurred previous to death. In an experiment made to distend the large intestine with water, the peritoneal cord in several places ruptured, before the muscular appeared inclined to give way under the pressure. This rupture of the peritonæum appears usually to commence over the transverse colon, and other portions are subsequently affected if the distension is continued.

This tendency of the peritonæum to rupture in rapid and great distension of the bowels, in cases of obstruction, indicates the importance of early interference, if any operation be considered desirable. When peritonitis has set in, in consequence of rupture of the serous membrane, or any other cause, operative interference would probably be too late to hold out any prospect of success.

4. Obstruction of the intestines occurs from a portion of bowel being strangulated in a loop, or bound down by a cord of false membrane; or it may be constricted by a diverticulum, adherent by its apex to some opposed surface of the viscera; or by the Fallopian tube, attached by its fimbriated process to some point of peritonæum; or by a thickened and elongated piece of omentum fastened down at the ends by adhesions; or by other accidental circumstances.

In an instance under the care of the author, a small ovarian cyst became suddenly dislodged from the pelvis, and from accidental circumstances, in its movement upwards it revolved so that its pedicle became twisted and consequently shortened. Symptoms of complete obstruction soon followed this displacement. When the abdomen was opened, it was found that the cyst lay just above the lower end of the ileum, and that the pedicle pressed so firmly upon the bowel that complete obstruction was thus effected.

All these conditions, favourable to the occurrence of internal strangulation, are generally the results of inflammation and effusion of lymph.

5. Peritoneal pouches, which have usually well-defined rings for their orifices, and the foramen of Winslow—but this rarely—have been the seat of obstruction and strangulation of the bowel.

The causes of obstruction mentioned in these latter instances are attended by symptoms entirely similar, and only require to be separated as regards their pathological conditions, but in treatment may be considered under one head. However, those obstructions which are due to the products of inflammatory action may occur at any time of life, but most frequently in the young, are very uncommon in old age, and are often found in children; whereas strangulation by a mesenteric pouch is usually observed in somewhat more advanced life.

Females are rather more liable to internal strangulation than males; for the appendages of the generative organs offer additional points for adhesive inflammation, and, consequently, entail so much more danger. In most, if not in all, of the conditions now under consideration, the small intestine is usually alone implicated.

The history and pathology of internal strangulation caused by false membranes and adhesions producing loop, &c., are best illustrated by the following cases:—

¹ *Pathological Transactions*, vol. x. p. 153.

² See the first case on p. 713.

A preparation in the Museum of St. George's Hospital shows the formation of a short band of lymph, adherent by one extremity to the free surface of a portion of small intestine; from this the band is seen to pass over another portion of small intestine, and then is immediately attached by the other extremity to the mesentery supporting the latter piece of bowel. As the effused band of lymph contracted, it so pressed on the portion of intestine which was crossed by the band, that entire stoppage of the bowels was produced.

A young lady, aged 19, died after a few days' symptoms of strangulation and vomiting. The omentum was firmly adherent to the anterior abdominal wall. This was the result of old adhesions. The small intestines were greatly distended. At the lower part of the abdomen, on the right side, and dipping into the pelvis, a large portion of sphacelated intestine was seen. This was about five inches in length, and consisted of the ileum, which was constricted and strangulated by a ring formed by lymph which had been effused in some former attack of inflammation. The ring was so firm that it was obliged to be cut through to liberate the intestine. It was formed by the band of lymph being attached by one extremity to the inner surface of the *caput coli* and stretched across to the ileum, to which it adhered by the other.

A child 4 years of age died after five days' constipation and symptoms of internal strangulation. The cavity of the abdomen contained some serum deeply tinged with blood. At the lower part of the belly several convolutions of small intestine were highly congested and dark-coloured; this to the extent of a foot in length, and one portion of it was almost black in colour. This latter portion was found strangulated by a band of false membrane, which was attached by one extremity to the point of an appendix, by the other to the mesentery. The appendix was attached to the lower portion of the ileum, and was about an inch in length, and communicated with the bowel. The appendix, and the band with its attachments, formed a complete ring about an inch in diameter.

A man, aged 20, died after fourteen days' complete constipation. Near the termination of the ileum, a portion of it, nearly two feet long, much distended and much darker than the rest, was firmly constricted by a narrow band (not thicker than whipcord), which passed from the vermiform process to the ileum close to its mesenteric attachment.¹

In a case in which a portion of small intestine was strangulated through a loop in the great omentum, perforation of the bowel had taken place, and had allowed the escape of *feces*.²

A man, aged 68, was admitted into St. George's Hospital on March 7, 1861. He had been lifting some heavy iron about eight days previously, when he felt a sudden strain, and immediate severe pain in the loins and belly. He passed a restless night; the next morning there was slight action of the bowels. He complained of pain chiefly in the belly and dragging at the umbilicus; there was also constipation from the second day of pain. Four days after the attack he first vomited; but now everything taken was rejected. The skin was cold, and eye sunken; there was blueness of surface, and the pulse was small and weak; the tongue dry and brown, abdomen enormously distended and tympanitic. No stricture could be detected through the rectum. An enema-tube would not pass readily beyond a short distance. Mr. Johnson decided to open the descending colon, with a hope to relieve the distension; but the bowel, when cut down upon, was found collapsed. The question of making an exploratory opening in the abdomen from the front was considered, but decided against. The patient died on the eleventh day. The small intestine was very vascular. At the lower part of the ileum, close to the ileo-cæcal valve, a band crossed the small intestine, forming a ring around the gut and the commencement of the mesentery. The origin of the ring was observed to spring from the sigmoid flexure, which was drawn over to the right iliac region so as nearly to touch the cæcum. The tissue forming the ring was loaded with fat, closely resembling the structure of an epiploic appendix. The other appendices were very long and broad, and some were perforated at their base, and presented an incipient condition of such a ring as had embraced the intestine. There could be little doubt that this ring was either formed in an appendix, or was formed by the adhesion of two neighbouring appendices. The gut, where it was bound down, was deeply marked by the stricture. From the stomach to the situation of the obstruction the bowel was greatly distended, but more particularly at the lower part, where for about a foot in length it was stretched so tight that it burst under a stream of water thrown in to wash it out; and was nearly black from congestion. The constricting band was not adherent to the intestine, and after removal from the body the gut could be easily moved backwards and forwards in the ring. The position of the obstruction was immediately over the right common iliac artery. The cæcum and upper part of the large intestine were of the natural size, and contained *feces*; the transverse and lower portions were empty and contracted.³ The external wound was just below the left kidney.

Strangulation of bowel through the foramen of Winslow is most rare. We cannot point to any case within our own experience.

Obstruction caused by bowel becoming entangled or caught in a mesenteric or meso-colic pouch is not so unfrequent.

¹ *Path. Soc. Trans.* vol. ii. p. 62.

² *Ibid.* vol. i. p. 250.

³ *Ibid.* vol. xii. p. 111.

A specimen of meso-colic hernia, which had not been attended by strangulation of the bowel, was exhibited at the Pathological Society, by Dr. Peacock, in 1849; having been removed from the body of a man aged 30. The left half of the transverse colon was deflected in a longitudinal direction, down the middle line, to the brim of the pelvis, and pushed forward by a large swelling, which projected on each side of the displaced colon. None of the small intestines were to be seen; but were found concealed in the swelling. This proved to be a large pouch formed by a fold of the meso-colon. It was opaque below, but the convolutions could be detected through it at the upper portion. The jejunum entered the pouch at the upper and posterior part; and the ileum passed out below and on the right side, about two inches above the termination of this portion of the intestine. There was no evidence of constriction of the bowel; nor did the displacement appear to have been productive of any inconvenience or disorder.

A second similar case was attended by strangulation of the intestine, and death. A man, aged 27, was seized with pain in the abdomen, and vomiting. He vomited everything taken, and the pain in the stomach was most severe. He died about forty-one hours after the commencement of the attack. The descending colon was found lying on the left side of the cæcum, and the small intestines were contained in a large pouch formed in the left meso-colon, and situated on the left side of the corresponding large gut. The ileum passed out of the pouch about two inches above the cæcum, and at that point the bowel was contracted, thickened, and gangrenous.¹

We have next to consider the symptoms and diagnosis of such causes of obstruction as have been already referred to. The symptoms in all such cases are, as a rule, very acute in their character; and prove rapidly fatal if not early relieved. A twist of the *large* intestine, in its first onset, may to some slight extent be an exception to this rule; but even in such an instance the more acute symptoms will surely appear at a comparatively early stage unless the obstruction be removed.

But, to whatever cause obstruction may be due, the symptoms are commonly so similar, that a correct diagnosis as to the exact seat or actual cause of the block is not often to be expected. We may, by careful inquiry and examination, approach somewhat near it. But, whether occasioned by intestine entangled in a loop, or fissured omentum; by a cicatrix or simple stricture; by a foreign body, or by a twist contracting a portion of gut; the symptoms will not vary much in character, though they may somewhat in degree, as well as in the periods of their commencement and sequence. Tension of abdomen, pain, absence of all abdominal movements, constipation and distension, with the coils of intestine often defined on the thin abdominal wall, and persistent vomiting; each and all may be present, and should be present to constitute the conditions of absolute obstruction. Vomiting, however, must always be looked upon as the most important indication of the completeness of the block. Its early commencement and its persistence indicate more than any other single symptom the urgency of the case, and the vital necessity of some immediate interference if life is to be saved by any available surgical means. In all internal strangulations, it must ever be borne in mind that the symptoms are always acute; pain is sudden, sharp, and occasionally agonising; vomiting sets in early and is usually incessant. At first the contents of the stomach alone are rejected, but if not soon relieved, fluid with fecal odour and in large quantity will now be brought up. The distension may not be so great, as often occurs in the more slowly operating causes of obstruction; but still the small intestine, above the seat of block, will become much loaded; there is generally great tenderness on pressure, for peritonitis is not long delayed; the abdominal muscles feel rigid to the touch, there is early evidence of grave constitutional damage, anxious and drawn countenance, especially in children, for the portion of intestine at the strictured part may soon thicken and inflame, or rapidly congest and mortify. The increasing distension of the upper bowel which occurs as long as the block lasts adds materially to these evils.

In the first instance in the early period of suspicion of obstruction, purgatives should be scrupulously avoided. This precaution cannot be too rigidly attended to at the commencement of symptoms. If there be a golden rule to guide us in the treatment of cases of obstruction it is this— that opium be administered by the mouth, and aperients by the rectum alone. Every rule may have an exception, but experience has taught us, that whenever this rule has been departed from occasion for regret

¹ *Path. Soc. Trans.* vol. ii. p. 60.

has followed. In addition to the internal use of opium, enemata should be used early and freely. Their administration will soon prove whether the lower bowel is free and capable of retaining a proper quantity of fluid, or whether, when this is returned, there comes with it any fecal matter indicative of some escape from above.

In twists of the large bowel, should an injection be used and not be returned, its repetition will but add to the evil; for fluid can sometimes be injected into the twisted portion, and yet is not capable of being returned. After the lower bowel has been thoroughly washed out, and the subsequent enemata return in much the same condition as they were injected, it will clearly indicate that no further passage of feces is likely to be effected by their continued use. The persistence of vomiting should then decide the question that no further relief can be obtained without an exploratory operation. Given the distension, arrest of all fecal discharge, and persistent vomiting, no other conclusion can be arrived at but that absolute obstruction exists. Under such circumstances, if life is to be saved, there is no alternative, after all other measures have been tried and failed, but to seek the seat and cause of the evil through an abdominal opening, and endeavour to relieve it. Delay is now dangerous, and the earlier the operation is performed the greater the chance of recovery for the patient.

To decide on this operation sufficiently early is the important responsibility thrust somewhat suddenly on the medical attendant. It too often occurs that the operation is too long delayed to render it successful. Its performance is of so serious a character, and the nature of the obstruction usually gives so little time for consideration, while a chance of successful relief from operation lasts, that we cannot impress on the practitioner too strongly the importance of early action under the circumstances mentioned. It must never be lost sight of that incessant vomiting is essentially the most important symptom, as indicative of a block which necessitates an operation for its relief. If allowed to continue, it is in itself a source of extreme exhaustion: if allowed to continue until it becomes fecal in character, still less hope can be entertained from the effects of an operation. Fecal vomiting not only indicates the serious character of the block, but also that that block has existed, comparatively, some time. It may have been long enough to permit the commencement of gangrene, or to have set up peritonitis sufficient to banish the small hope we might otherwise entertain that an operation held out some prospect of life. Delay in operating accumulates danger after a patient has been known to vomit a few times. Peritonitis established without even a gangrenous condition of bowel is a formidable antagonist after an operation, even with perfect liberation of the stricture.

In the treatment of external strangulative hernia, when reduction cannot be otherwise effected, we have made it a rule invariably to operate as soon as vomiting had set in. Our maxim has been, *never to allow a patient to vomit three times*, but to operate as soon as vomiting commences, if called in sufficiently early to carry out this treatment.

In all these cases—acute obstruction; from whatever cause—the operation, being decided on, should be conducted in the usual method of opening the abdomen, by an incision commencing in the median line just below the umbilicus, and carried down two or three inches towards the pubes. Should this opening not prove sufficient to enable the operator to ascertain the seat or cause of obstruction, it may be enlarged upwards or downwards, as most convenient under the circumstances. The protrusion of distended bowel will often prove a difficulty in this stage of the proceeding, but the intestine may generally be held aside by an assistant sufficiently to enable the operator to explore the abdomen with finger or hand.

It will often be found difficult to detect the seat of the block without following the course of the intestine; the operator will generally find that this is more readily effected by commencing from below, and tracing up the contracted and empty gut, than to endeavour to follow down from above the distended portion, till the seat of stricture is reached.

It is almost impossible within our limits to lay down absolute directions as to the measures to be adopted in the various conditions which may be met with under

many circumstances; much must be left to the discretion of the operator to overcome whatever difficulties he has to encounter. If one portion of small intestine is distended and another contracted, the probability is (intussusception excluded) that the cause of obstruction will prove to be some form of internal hernia, or a band constricting, rather than any stricture of bowel. In the former case it is usually not difficult to reduce the strangulated portion by gently pulling on the collapsed portion, and we have succeeded in doing this without the slightest trouble, after internal strangulation, dependent on a loop of the small intestine entangled in a pouch in the mesentery. In this instance it was most interesting to observe, as soon as the obstruction was relieved, the collapsed bowel commence gradually to become inflated from the passage of air into it from the bowel above.

If the obstructing cause be due to a band, this should be divided at whatever may be considered the most desirable point; and should there be any evidence of bleeding from the cut surfaces, it is best at once to twist the vessels, or apply fine catgut ligatures to the bleeding points, or even prior to the division of a band, if large or broad, ligatures may be applied in either side of the proposed line of division. The removal of a tumour will of course be requisite if the cause of obstruction, as occurred in the practice of the author. In this instance the pedicle of an ovarian cyst lay over and compressed the ileum. In twists of the bowel it is not generally difficult to detect the evil after the abdomen is opened. Some care is requisite in handling the distended intestine. Its distension produces a softened condition of its coats, and under such circumstances the bowel is very apt to be torn or to rupture, unless very carefully manipulated. Twists of intestines must always be considered as most severe and grave conditions to deal with, and do not offer much hope of benefit from operation; still the effort should be made, as we are quite unable by any other means to relieve the obstruction. In the case of a foreign body being impacted in the bowel, there is no alternative but to remove it. If practicable, the portion of bowel in which the obstructing mass is lodged should be carefully drawn out of the abdomen; the intestine may then be opened, the substance removed, and then the orifice in the bowel closed by a continuous suture of fine silk or catgut. This subject will be found fully discussed under the head of INJURIES OF THE ABDOMEN.

The obstruction being removed, the margins of the abdominal wound are to be brought together in the usual manner, by sutures passed through its edges so as to include the peritoneal surfaces, and the surface dressed with dry absorbent cotton, and flannel bandages lightly placed round the body. The patient should be kept fully under the influence of opium for some days, the water drawn off if necessary every four hours, and the bowel not interfered with for a week, and then only by enemata. Very small quantities of fluid food, with ice to allay thirst if requisite, should only be permitted for the first six or eight days.

Such are the general rules applicable to acute cases of obstruction, and which will be found with few exceptions to be confined to the small intestine.

We have next to consider another cause of acute obstruction, which may implicate small and large intestine. We refer to—

6. *Invagination*, or intussusception of the bowel, is often the result of irritation caused by worms; of tumours attached to the mucous membrane; and of other accidental causes, not always to be detected or explained.

Invagination may frequently be observed in the post-mortem examinations of children. It also often takes place in grown-up persons of all ages and of both sexes, and in almost every portion of the intestinal canal.

Invagination may occur in one or in several parts of the bowel at the same time in the same individual; but when, on examination after death, several intussusceptions are met with, they are usually slight, and have not been productive of urgent symptoms during life.

In illustration of some of the causes of intussusception, the following examples are worthy of record:—

In the Museum of St. George's Hospital is a preparation, which shows an intussusception caused by the presence of a tumour growing from the wall of the bowel and projecting into

its cavity. A process of sloughing has nearly detached the prolapsed portion from the rest of the intestine, and so almost set free the tumour. The patient died of peritonitis.

Another preparation in the same Museum displays a portion of small intestine invaginated, apparently from the irritation set up by an *ascaris lumbricoides*, which may be seen coiled round the prolapsed portion. But many other parts of the bowel were also invaginated; and when the patient died, the state of the bowel was not suspected.

The anatomy of intussusception is interesting. The usual form of intussusception met with is an inversion of a portion of intestine into the tube of the gut immediately below. But the relative conditions of the upper and lower portions of the bowel may be reversed; the intestine below may be projected into the intestine above, and this would still constitute an intussusception. This latter state, however, is exceptional; the former is not uncommon, and may prove fatal if not relieved.

Fig. 158.—Intussusception, caused by the Traction of a Fibrous Tumour of the Intestine.

A perpendicular section through an invagination will display on each side, and lying parallel with each other, three layers of intestinal wall; a transverse section would show these rings of intestine, one within the other. In each section, whether perpendicular or transverse, the opposed surfaces of the intestine will correspond in character; peritoneum will touch peritoneum, and mucous membrane be in contact with a similar tissue. The outer surface of the external layer is peritoneum; the lining of the inner layer is mucous membrane; but between these there are two opposed surfaces of mucous membrane, and two likewise of peritoneum. Between the inner and middle layers, and in the space lined by peritoneum, will be a certain portion of mesentery or meso-colon dragged in by the inner layer of bowel as it becomes prolapsed. The limit of the invagination above is at the outer or peritoneal surface of the bowel, and consists of an obtuse edge, formed by the folding in of the intestine at that point. The lower limit is inside the tube, and can only be observed when the gut is laid open. The portion of intestine which receives the invagination is a single layer, the invaginated portion, that which slips into the former, consists of two layers of bowel. A portion of mesentery will be found between these two layers, its size and shape varying with the length of the prolapsed intestine. The

lowest extremity of this impacted mesentery is almost drawn to a point, and is near the extreme lower part of the prolapse. The mesentery is thicker and broader where it enters the fold between the two layers of intestine, so that it becomes somewhat triangular in shape as it lies between the two layers of intestine already alluded to. As the mesentery is attached to one margin of the bowel, the bowel in prolapsing is somewhat retarded by the mechanical action of the former; for the mesentery, being always in a state of tension, drags upon one side of the prolapsed bowel; it will therefore be found, especially in an extensive prolapse, that the prolapsed end of the gut, its inner extremity, is turned in the direction of the attached mesentery; from which circumstance the piece of bowel presenting the prolapse will be found slightly curved to one side, and thus the whole mass assumes a crescentic figure.

Rokitansky, in referring to this condition, makes the following important remarks:—
‘Firstly, that the invaginated portion does not lie parallel with its sheath, but always

offers a greater curvature than the latter, the inverted tube being compressed on its concavity into tense transverse folds. Secondly, that the orifice of the invaginated portion of bowel does not lie in the axis, or in the centre of the sheath, but towards the side; and that, following the traction exerted upon it by the mesenteric fold that belongs to the inverted intestine, it is directed towards the mesenteric wall of the sheath; that the opening is not circular, but represents a fissure. This affords a diagnostic sign for the examination of intussusceptions of the rectum, which are within the reach of manual exploration.¹

Though intussusception may occur in almost any part of the intestinal canal, it is most frequently found towards the middle and lower portions of the small intestine, and may implicate any portion of the large bowel. When an intussusception increases in size, the involution is usually that of the bowel below the commencement of invagination; if this commences at the lower part of the ileum, more of the upper ileum does not disappear, but the prolapse grows in length at the expense of the inferior portion of the intestine. It will frequently be found to extend to the rectum, whether commencing high up or in the descending colon, and may even protrude through the sphincter. Should it originate in the lower part of the ileum, it may continue downwards so as to involve the ileo-cæcal valve, cæcum and colon more or less.

A boy, nearly five years of age, complained of soreness about the anus, the result of ascarides. The next day he was seized with sudden pain in the lower part of the abdomen, and strained several times at stool, but passed nothing. He soon afterwards vomited. He continued to go to stool every half-hour. In the afternoon he experienced constant desire to go to stool, and passed a clot of blood. On some of these occasions he passed dark-coloured blood and slimy matter. There was great restlessness, and thirst. The abdomen was more swollen above than below the umbilicus. There was much tenderness over it on pressure. The symptoms continued unrelieved, and death took place on the fifth day. A considerable intussusception had occurred of the ileum through the ileo-cæcal valve; the appendix was also carried in. About 3½ inches of bowel protruded into the cæcum. The involved part was of a deep red colour. It was so firmly grasped by the ileo-cæcal valve, that the effort to reduce it appeared likely to tear the bowel.²

A child, six months old, died after sixty hours of suffering from vomiting and discharge of bloody mucus from the rectum. The whole of the colon, ascending transverse and descending, had passed into the sigmoid flexure. The mucous membrane of the prolapse was purple from strangulation.³

The two foregoing cases mark the prominent symptoms of acute invagination of intestine; sudden pain; constant and urgent desire to stool, with little fecal matter passed, but blood in clots or bloody mucus escaping in small quantities; more or less vomiting, great distress, both general and local, and death following in a few days. But death may be somewhat sudden.

A sailor, during a railway journey, was observed to place himself on the floor of the carriage, but had no attention paid him by his fellow-passengers. At the journey's end he was found dead. The abdomen presented marks of severe peritonitis. A fold of intestine near the termination of the ileum, six inches in length, was intussuscepted and gangrenous. Probably in this instance the mischief was of some few days' duration.⁴

It will thus be seen that intussusception may be confined to a comparatively small portion of the small intestine, while at the same time the obstruction may be as complete as it is sudden; or it may implicate both small and large bowel, and yet the symptoms may not be urgent till some days, or even some weeks, have elapsed, and ultimately prove fatal.

In the first instance the case may be distinguished as *acute*; the symptoms will be severe soon after the attack, and indicative of complete obstruction and strangulation, to be rapidly followed by the death of the part; which may be thrown off and be passed by stool, and the patient recover, or may be followed by perforation of the bowel and the death of the patient. In the other case, though some of the symptoms of invagination may be present, there need be no absolute obstruction for weeks following the commencement of the invagination.

In other instances the symptoms appear to extend over a much longer period,

¹ *Path. Anat.* vol. ii. p. 55.

² *Ibid.* vol. ii. p. 56.

³ *Path. Trans.* vol. ii. p. 55.

⁴ *Ibid.* vol. i. p. 77.

and ultimately prove fatal: or if the strangulated bowel slough off, may terminate favourably.

A man, aged 25, suffered from attacks of colicky pain in the abdomen, and gradually lost flesh. One day he became suddenly worse, and on the following day died; nearly four months from the supposed date of the commencement of his attack. About six inches of ileum, cæcum, and the first part of the ascending colon, had passed into the large bowel beyond. There was no appearance of gangrene in any part. The colon contained much mucus and coagulated blood. The mucous membrane was turgid and purple. The involved layers of the intestine were firmly adherent to each other by dense bands of false membrane.¹

The separation and passage of the strangulated portion, with recovery, is a result we may occasionally anticipate, and it has been known to occur in some few cases; ~~for~~ does the loss of the piece of bowel appear to be attended by any subsequent evil consequences.

A boy, aged 5, was taken ill four months previously to the time at which a mass of bowel was passed. At first he suffered from simple fever, but afterwards experienced much distress. He complained chiefly of pain in the region of the bladder; but there was no tenderness. The urine was sometimes retained for a long time. The bowels were very much confined, sometimes for fifty hours. There was occasional vomiting. He was never known to pass blood. *Eight inches of the ileum, the cæcum with its appendix*, and about four inches of the colon, were passed by stool. The tissues were almost black, and offensive. Diarrhoea preceded the discharge of the separated bowel. At the end of six weeks from this event the little patient seemed quite well, and the bowels acted regularly.

This case occurred in 1847, under the care of Mr. Heslridge Buckby, of Sutton-on-Trent. In September 1863, he kindly wrote to the author to the following effect: 'I have much pleasure in informing you my little patient has continued in perfect health ever since his restoration. I saw him the other day.'

V. T., aged 18, was seized with severe paroxysmal pain in the abdomen. This continued and increased without relief; and was followed by stercoraceous vomiting. Symptoms of general peritonitis came on, without any relief from the bowels. The more urgent symptoms were relieved under the use of calomel and opium; but no evacuation was obtained. On the tenth and following day enemata were returned without any fecal tinge. On the twelfth day some feculent matter was brought away, and more feces passed after a dose of castor-oil. On the nineteenth day he had three motions. The last consisted of bright florid blood, mingled with many portions of the small intestine. The two previous motions were said to have been of precisely the same character, and to have contained many 'skins.' At the expiration of six weeks the patient returned to his usual occupation.²

Peritonitis may be the result of perforation of the bowel during the separation of the sloughing prolapse, in which case acute pain and much suffering are generally followed by rapid death.

It will appear that, although invagination has been classed with the causes of acute strangulation, many cases occur in which the symptoms are not very acute, last some time, and even terminate in recovery, though at a sacrifice of a portion of the bowel.

The general symptoms of intussusception are usually pain referred to the seat of the mischief, often of an acute character, sudden in its attack and confined in its extent; constant and often urgent desire to evacuate, but without satisfactory result; scanty motions more or less mixed with mucus and frequently with blood; generally a swelling, sausage like in shape, is to be felt in or near the position of the ileo-cæcal valve; constipation according to the amount of obstruction; and vomiting when obstruction becomes entire; then also will distension of the bowel follow, and gradually become more and more evident. In the more chronic case distension may not occur, and will most probably be but slight, if at all present. No age is exempt from invagination, but children are most liable to its occurrence. In a table, drawn up Mr. Hutchinson, of 131 cases, 90 occurred in children of six years of age and under.³

The pain in such instances is often intermittent, but well marked; when present, the child doubles itself forwards and often rests its head on the bed, kneeling. Intussusception without strangulation may not even be suspected for some time after its commencement; in some cases not until the end of the invaginated bowel is

¹ *Path. Trans.* vol. vii. p. 193.

² *Ibid.* vol. vii. p. 190.

³ *Med.-Chir. Trans.* vol. lviii.

detected in the rectum, or has made its appearance through the sphincter. But in all acute cases there will be early passage of blood, distension of the abdomen from the bowel above the block becoming dilated by fluid and flatus; constant desire to defæcate without the trace of any fæculent matter in whatever is passed; continuous vomiting of all fluids taken by the mouth, and that ejected becoming fæculent odour if the patient survives many hours. The obstruction being fully established, nothing but blood or bloody mucus will be passed per anum.

In the more chronic form, as the invagination increases (which is always the case) and is allowed to remain unrelieved, without any general symptoms of obstruction, a change will probably gradually occur which will render it incapable of being reduced. This change is usually rapid in the acute form, but may not occur for some weeks in a chronic case. From pressure exerted on the coats of the bowel and its mesentery, congestion followed by inflammation is sooner or later liable to occur. One result of this is a more than natural secretion from the mucous surface of the entangled piece; frequently the discharge is mixed with blood; a symptom of much importance in the diagnosis of intussusception, for we may safely say the greater the proportion of blood the more complete the obstruction. But as the invaginated mass becomes thickened the peritoneal surfaces become gradually adherent to each other, commencing at or near the entrance of the upper ring of the sheath. At this line there will also be a certain amount of strangulation exerted upon the portion within the ring. This is the first step made by nature to remedy the evil, if it be not otherwise relieved, so that presently the prolapsed portion may be cast off by slough, and also that the escape of the contents of the bowel may be provided against, by the cohesion and subsequent union of the upper and lower portions of what would otherwise be a severed intestine.

From what has been already said, it will be apparent that it is a very important point in practice to be able to diagnose between the more acute cases in which strangulation early ensues, and the more chronic forms of invagination, in which much bowel may be implicated and yet give time for hopeful interference. Whatever portion of bowel be involved, and to whatever extent it may be implicated, the first thing to be done in the investigation of a case, given the general symptoms, is to examine the bowel per rectum; frequently the lower end of the involuted part will be there detected by the finger. This will at once be diagnostic of intussusception, although it may not indicate the extent of bowel involved. If no evidence of prolapse be found in the rectum, it is next desirable to examine carefully the surface of the abdomen in order to detect any swelling caused by the invaginated mass. This often is not difficult to discover, but, should the resistance of the abdominal muscles or the distended state of the bowels obscure its position, the use of an anæsthetic will prove advantageous by relaxing abdominal rigidity, and generally will enable the surgeon to detect the seat of obstruction by the presence of some swelling or hardness. The prolapsus having been detected in the rectum, or suspected elsewhere from the existence of a tumour and general symptoms of invagination, enemata of warm water or injection of air may be tried with a hope to overcome it. The pelvis of the patient should be well raised during this time, the better to retain the fluid, and thus by its weight to assist in the attempt at reduction. If the prolapse be suspected to be confined to a portion of the lower bowel alone, the introduction of a bougie may possibly reduce it; but the experience of the author entirely confirms the following observation of Mr. Hutchinson's, 'I have not found any case recorded in which spontaneous return of a well-recognised intussusception occurred; and those in which art succeeded are comparatively rare.'¹ But as a rule when extensive invagination has taken place no amount of injection or use of bougie will prove useful, beyond the fact that the return of the injected water, if unmixed with fæculent matter, is a pretty clear index that complete obstruction exists; or, if mixed with even a small amount of fæces, the condition is such as to leave more hope of relief by operation. The mechanical condition of a large portion of invaginated bowel renders it perfectly

¹ *Med.-Chir. Trans.* vol. lvii.

hopeless to expect any benefit from any treatment short of operation, supposing, of course, that the invagination has not already been relieved by slough.

In the last edition of this work the author supported the view that it were better to allow a case of intussusception to run its course, with the prospect of its being relieved by slough, rather than to interfere by abdominal section with the hope to relieve it. Since then several cases have been operated on with varying success by several surgeons, and also by the author. The result of this conjoined experience is, that in many cases the operation is to be advocated, should certainly be undertaken, and may probably prove successful.

But, as Mr. Hutchinson has pointed out, some discrimination is needed in the selection of cases for operative interference. He has properly classed cases of intussusception as those which are early marked by symptoms of *strangulation*, and those which are simply *irreducible*, except by surgical interference. 'The former tend rapidly either to the death of the patient, or his relief by gangrene of the constricted part.'

It is only in the more chronic cases that operative interference is likely to prove beneficial. In the more acute cases in which complete strangulation has occurred, made evident by entire stoppage of fecal matter, passage of blood only, and continued vomiting, unless an operation be performed for its relief very early indeed after intussusception has occurred and is detected, it will probably prove a failure, for when the bowel is attempted to be unravelled, the parts, from having become matted together, render reduction impossible. Such was the case in an instance under the author's immediate observation, although the operation was performed within forty-eight hours of the commencement of the stoppage. In this case it was found impossible to reduce the invagination either from below or from above, without the application of force which would have torn open the bowel, the mesentery became slightly lacerated in the attempts made at reduction. The child nearly died on the table, before the wound of the abdomen was closed, and only survived the operation a few hours. Mr. Hutchinson remarks that, 'if the operation were resorted to in cases of acute strangulation, there would always be a risk that the surgeon might find the parts in a state of gangrene, and might discover that he had interfered only to take away the patient's last chance.'

In the more chronic cases, however, the operation should be at once attempted when other measures for the reduction of the bowel have not proved successful, for we know from experience that there is no possible chance of reduction of the prolapse if left to nature, and that the longer it is left unrelieved the greater the chances of adhesion, exhaustion, or even gangrene.

The operation of opening the abdomen for the relief of intussusception is in all respects similar to that for any other form of obstruction, and has been already described. But with regard to the prolapse itself, it is necessary to say that some difficulty may be encountered in the attempt to reduce it. As in the management of obstruction from other causes, so in intussusception, we have found it most convenient and more easy to follow up the empty portion of bowel from below the seat of obstruction, and to draw upon it when arrived at that point, rather than endeavour to effect the reduction by manipulating and drawing upon the upper and distended bowel.

It must ever be borne in mind that to open the abdomen in any case of obstruction is a very serious undertaking; in almost all its aspects more serious than abdominal section for the removal of a tumour. Prior to operation in the latter case the intestine can always, and always should, be emptied; in many instances during the operation the intestines are hardly seen, and but little exposed; we remove what is often a source of much local trouble. In the former the intestine above the obstruction is always somewhat distended, often greatly distended. The patient, too, is already more or less exhausted by vomiting, if not by some greater and graver evil dependent on the prolapse. Without such complications, the simple abdominal section in one of tender years

—it may be even in one of infancy—is of itself a very serious risk, when it is recollected that the bowel must be exposed to a great extent. Under such conditions a serious depressing influence is produced by this exposure. The protruding and distended intestine may also become a source of trouble, even after the invagination has been reduced, for difficulty is occasionally experienced in replacing the bowels within the peritoneal cavity. This may greatly prolong the operation and add to the exhaustion of the child. Even when much distended, we would prefer not to puncture the intestine, if it be possible to avoid doing so. After such a puncture a patient has been known to recover, but on the other hand the puncture has been known to prove fatal, by allowing the contents of the bowel to escape into the peritoneal cavity. If it should appear impossible to replace the bowel without in some way or other diminishing its calibre, the most prudent step is to puncture it with a fine trocar, and, previous to the intestine being returned, to secure the punctured point with a ligature, so that the best possible precaution be taken to avoid the escape of its contents.

We have now to consider the more chronic conditions productive of obstruction.

1. Habitual constipation may become accidentally prolonged to such an extent as to cause anxiety; or the accumulation of fecal matter may be mistaken for a tumour, so circumscribed occasionally is the collection in the large intestine. The time which may elapse while the bowels are entirely closed, and the amount of feces which may be collected therein, would surpass belief, were it not that the experience of those now living can confirm the statements made by writers on this subject.

A lad, aged 7, on recovering from an attack of fever, was affected with great torpor of the bowels. This gradually increased to such an extent that in two years treatment failed to have any effect. When admitted into the Free Hospital, under the care of Mr. Gay, it was stated that *nothing whatever had passed from the bowels for three months*. The health had not suffered; the appetite was good. The body was greatly enlarged, and was forty-nine inches in girth; and there was inconvenience to respiration. There was considerable prominence on the left side, as if the colon and sigmoid flexure were chiefly loaded.

A speculum was passed into the rectum, and, after dilating it, an enema tube was passed high up. The contents of the bowel were washed out by a stream of warm water kept constantly playing upon them, for half an hour at a time. A large quantity of hard black feces, like cinders, was brought away. These measures repeated several times reduced the girth of the abdomen to twenty-six inches.¹

The surgeon is usually consulted at the latter period of obstinate constipation, which has at last arrived at complete obstruction of the intestine; and as all power of propulsion is then lost, the contents have to be removed mechanically. This can only be done by the aid of repeated warm-water enemata; or by means of some kind of scoop or short lever, with which the lowest masses of hardened feces should be carefully dislodged. The sphincter muscle is often excessively irritable and painful under these conditions. The use of an anæsthetic will then be found most advantageous.

Purgatives in such cases are not of much use, until the load is somewhat reduced in the lower bowel.

The following very instructive case is mentioned, in a letter to Dr. Burne, by the late Dr. R. Williams, Physician to St. Thomas's Hospital. A lady, aged 35, was attacked with severe gastrodynia, and most obstinate constipation. Paroxysms of pain recurred at short intervals, gradually became more frequent, and at length quotidian. Each meal was followed by pain so severe and continued that she limited herself to dry biscuit and brandy-and-water; and this was commonly rejected. Nothing gave relief but opium, of which, for months, she took not less than sixty grains daily. Her bowels, independent of the astringent effects of opium, were always greatly constipated; and no quantity of salts, oil, or senna in the least moved them; elaterium, croton-oil, or other powerful purgatives immediately inverted the action of the stomach, and were rejected. Calomel was the only medicine which would act upon the bowels, and this not until her mouth was affected.

From this cause she frequently had no evacuation for *six weeks* together; and in one year, when much weakened by repeated salivation, so that it was necessary to defer the administration of the calomel as long as possible, she had only one evacuation every *three months*, or *four in the year*.

At the times her bowels acted she suffered immensely, her pains being more severe, if

¹ *Path. Trans.* vol. v. p. 174.

possible, than those of labour. The fecal matter when passed was enormous in quantity, healthy in colour, and was formed into large round lumps or scybala, each certainly not less than a large foetal head, and so numerous as often to fill a common-sized pail.¹

We may, perhaps, have travelled somewhat from the path of our especial calling, in introducing the latter cases, illustrative of chronic obstruction of the intestine. But the accumulation of large quantities of feces is often productive of a strange and anomalous train of symptoms; often such as indicate structural obstructions; or simulate morbid growths in the abdominal cavity, and even retention of urine from pressure on the urethra, &c., as occurred in a case under the author's notice, in which the rectum was enormously distended by hardened feces. Experience, discrimination, and careful examination are often requisite to insure a correct diagnosis as to the true nature of these collections: and without extreme caution, the surgeon may be baffled in his attempts to unravel the conditions attendant on a loaded intestine, accompanied by obstinate constipation. With a gut greatly distended by fecal matter, and with the symptoms of organic obstruction, it will frequently happen that the bowels act freely, and yet without relief, or any reduction of the size of the abdomen. It is but the over-shot of the sluice: the head-stream is dammed up; the canal is loaded to over-flowing.

2. Obstruction, the result of injury, we need but allude to here. The conditions and treatment have been already described; see Vol. I. INJURIES OF ABDOMEN.

3. Constipation, occasionally amounting to obstruction of many days' standing, or even of a fatal character, is apt to occur in cases of peritonitis, attendant on tubercular deposit in the subserous cellular tissue, or the result of other causes; a condition often accompanied by ulceration of adjacent and adherent surfaces of the intestine.² A direct communication thus takes place between two or more opposed surfaces of bowel; often an abscess is found within the abdomen, communicating through ulcerated openings with several portions of the intestinal canal; there is great irritability of the stomach, and often rejection of all food; an unyielding abdominal wall and an irregularity of its surface; general but not exquisite tenderness; and constipation of, perhaps, some days' standing. Such symptoms might at first sight convey the idea that obstruction was due to some of the causes previously enumerated. But in such cases as we have now under consideration, there are usually general indications of tuberculous cachexia long before symptoms of obstruction set in. The conditions of the bowels is, however, as a rule, extremely uncertain in these cases: occasionally confined, but more frequently relaxed. With adhesion of peritoneal surfaces, and ulceration through the coats of the intestines, obstruction is rare; and is rather the exception, unless the calibre of the bowels is contracted by the pressure of abscess, or diminished by false membrane, or other media, stretched across the tube. Looseness of bowels is the usual condition in the cases just considered.

4. Stricture of the intestine is the most common cause of obstruction.

Strictures of the intestine occur under various conditions, independent of cancerous deposit, in the walls of the gut. The chief causes of simple stricture are due to the action of caustic substances, to the presence of foreign bodies, causing ulceration and contraction; to tuberculous and syphilitic ulceration; to ulceration of the mucous membrane without any known cause; to the thickening attendant on an old reducible hernia; and to an inflammatory action taking place in the walls of a portion of the intestine, terminating in the effusion of fibrine, and subsequent contraction of the canal.

Stricture the result of disease of the upper portion of the small intestine is rare. We believe, when met with, it usually follows cicatrisation and contraction after ulcer, the direct effect of some escharotic swallowed; or of some other form of ulcer which, in healing, has narrowed the diameter of the gut.

Stricture of the duodenum is uncommon. We have met with a few instances of it. In the Museum of the College of Surgeons is a specimen of a stricture of the duodenum; the stricture is half an inch in length. It appears simple in its character, but has no history attached to it.³

¹ Burne, *On Habitual Constipation*, p. 28.

² An interesting case is recorded by Dr. Bristowe, *Path. Trans.* vol. viii. p. 200.

³ Series xxiii. No. 1170.

The following case well illustrates the effects of an escharotic substance introduced into the stomach. A woman, aged 40, accidentally swallowed about half a wineglassful of 'Burnett's solution' (chloride of zinc), and was immediately seized with violent pain and vomiting; but under treatment recovered from the immediate effects of the poison. A month afterwards, pain and vomiting returned; and in about two months after she was admitted into St. Mary's Hospital, under the care of Dr. Markham. All food taken was rejected; and she died about four weeks after her admission, and some three months after taking the fluid. In the pyloric portion of the stomach, about an inch and a half above the valve, the stomach was so contracted as only to permit the passage of a small bougie. The constriction was clearly the result of a cicatrix.¹

A young lady had accidentally some 'Burnett's fluid' given to her instead of a dose of medicine. Acute pain and vomiting were the immediate result, and for many months life was despaired of; by degrees the stomach became more tolerant of food, and was able to retain small quantities of fluid nourishment, taken at frequent intervals. It is now many years since the accident; but the greatest care was at first requisite on the part of the patient with regard to diet. It could then only be taken in a fluid form, in small quantities; and was generally required at intervals of four hours. Solid meat, or indiscretion in quantity of food, produced vomiting. The health was in every other respect good. Probably some contraction had taken place from ulceration, caused by the caustic applied to the pyloric extremity of the stomach or to the duodenum. Of late years the patient has been able to take solid food.

Stricture following other forms of ulceration is occasionally met with. A specimen of stricture of the ileum after ulceration is recorded by Dr. Bristowe. The ileum and lower part of the jejunum presented numerous ulcers, mostly cicatrising. At the commencement of the ileum a cicatrix had formed, and reduced the calibre of the intestine to such a degree that the point of the little finger could barely be inserted. Below, the bowel was contracted; above, it was considerably dilated. One slough, opening through the intestine, allowed the escape of feculent matter into the peritoneal cavity. The intestinal wall at the strictured part was an inch thick. Throughout the large intestine were numerous cicatrising ulcers. The history of the patient did not throw any light on the case. For some years she had been liable to sudden attacks of pain and constipation.

A man, aged 54, had been poorly for twelve months. At the commencement of that period he had suffered from an attack of fever, since which he complained of pinching pain in the bowels; the abdomen became swollen; and he lost flesh. He could take very little food; was constantly sick, but the bowels acted once or twice daily. A constriction of the ileum was found at the junction of the upper with the middle third, dependent on great thickening of the walls of the bowel. The stricture was an inch long, and barely admitted the tip of the finger. Immediately above this, the bowel formed a pouch, the parietes of which were thinned almost to perforation. In this pouch were found thirty-three plum-stones, and sixteen cherry-stones, all perfectly black; and half a dozen recently swallowed orange pips. There was an oblique inguinal hernial sac, into which it was evident, from the position of the parts, that the strictured portion of the intestine had been in the habit of passing.²

These cases are interesting when we consider the causes of the strictures described. In the former, though there was extensive ulceration of the bowel above and below the stricture, the symptoms, and the nature of the latter, incline us to believe that contraction of the bowel from cicatrix was the primary disease. In the latter case it is most probable that inflammation, produced by the bowel frequently slipping into the old hernial sac, was the original cause of the stricture, quite independent of the attack of fever, or any ulceration of bowel following that attack.

In allusion to this consideration, viz. whether the ulcerations of intestine in fever are subject to contraction, and are thus productive of stricture, Rokitansky observes that the cicatrices 'have occasionally been observed thirty years after the fever had occurred'; and he adds, 'it is singular and characteristic of this ulcer and its cicatrix, that they never in any way give rise to a diminution of the calibre of the intestine.'³

Of the healing of ulceration, the result of tubercular infiltration, he further observes: 'In consequence of the contraction of the ulcer, a cicatrix forms on the surface of the intestine, which presents a more or less elevated ridge on the internal surface of the intestine. If the ulcer was of considerable size, or if it encircled the entire intestine, a callous annular ridge remains, which diminishes the calibre of the intestine, and when viewed from without occasionally gives rise to an appearance of invagination. Thus the healing of a tubercular intestinal ulcer is always accompanied by a diminution of the intestinal calibre.'⁴

¹ *Path. Trans.* vol. x. p. 164.

² *Path. Anat.* vol. ii. p. 73.

³ *Ibid.* vol. x. p. 154.

⁴ *Ibid.* vol. ii. p. 96.

So, also, in the ulceration of the bowel under attacks of dysentery, he observes: 'In case of extensive destruction of substance, the approach of the edges is rendered impossible; the deeper layers of the tissue, which takes the place of the mucous membrane, is frequently condensed into fibrous bands, which form corded projections into the intestinal cavity, interlace with one another, and not unfrequently encroach upon the calibre of the intestine, in the shape of valvular or annular folds, thus giving rise to a stricture in the colon of a very peculiar form. This mode of regeneration is more remarkable, as it closely resembles that following the destruction of the œsophageal mucous membrane by mineral acids.'¹

A case of stricture of the sigmoid flexure, near its junction with the rectum, is reported by Dr. Peacock.² The contraction was apparently due to the cicatrix of an old ulcer. There was much thickening, puckering, and induration of the internal tunics. There was no appearance of any cancerous deposit. Immediately above the stricture the cavity of the intestine was very large, and an ulcerated aperture of sufficient size to admit the passage of the thumb existed on the anterior and inner side; a portion of fecal matter had escaped into the cavity of the pelvis.

5. Obstruction is too often the result of stricture, dependent on cancerous deposit in or about the walls of the intestine. The ultimate effects are equally fatal. Their treatment must vary according to their conditions: and life may be even prolonged many months with proper care and judicious management.

Cancer of the intestine occurs most frequently in the large bowel. When the small intestine is affected, usually the disease has attacked it secondarily, having originated in some contiguous tissue. The nature of the deposit varies much in different cases: epithelioma, true scirrhus, medullary deposit, or villous growth, will each be met with; the former more frequently than any other form of cancer; but, as Rokitansky justly observes, they 'may be combined with one another, from their first origin, or consecutively.'

'The colon,' he continues, 'is almost exclusively the seat of cancerous degeneration; but there is a gradation in the proclivity of its different sections to the affection. The rectum is most frequently attacked; in second order, the sigmoid flexure; and the remaining portion of the colon but rarely. . . . Carcinoma occurs as a primary affection of the intestine in three forms. Firstly, in the mucous membrane, as carcinomatous infiltration of the erectile tissue, into which the former has been previously converted—fungus; secondly, more frequently in the submucous cellular tissue, as round nodulated accumulations; thirdly, most commonly as an annular deposit of the cancerous tissue in the submucous cellular layer.'³ And he adds that 'cancerous stricture of the intestine is the most common variety of stricture that results from alterations in the intestinal coats, and at the same time the one that advances to the highest degree.'

Out of a total of thirty-one cases of stricture of the intestines examined after death at the Middlesex Hospital, in no fewer than twenty-seven was the disease situated in the large intestine. Of the remaining four cases, in one it involved the ileo-cæcal valve; in another the ileum at its lower end; in a third, the upper part of the ileum; and in the fourth the jejunum. Out of thirty-two cases recorded in the Pathological Transactions, thirty-one involved the large bowel alone, and one the lower end of the ileum and cæcum. In fifty-eight cases out of sixty-three, the seat of stricture was in the large bowel. In round numbers, nearly three fourths of the cases of stricture involved the lower end of the intestine, the number met with in the sigmoid flexure and in the rectum being practically equal; whilst of the remaining one fourth, the ascending colon is the rarest, and the cæcum the next rarest seat; the remainder being equally shared by the regions of the transverse colon and the descending colon.'⁴

⁴ *On Strictures of the Intestine*, by Sidney Coupland, M.D., and Henry Morris, M.A., F.R.C.S. Read in the Section of Surgery at the Annual Meeting of the British Medical Association, 1877.

The following case illustrates the history of such a stricture :—

A man, aged 58, was admitted, under the care of Mr. Birkett, into Guy's Hospital, with constipation, which had existed for a week. Twelve months previously the patient had been attacked with diarrhoea, sickness, and great pain over the whole of the abdomen. The diarrhoea ceased, but the attacks of sickness and pain recurred at intervals. He lost flesh. The bowels were sometimes costive, at others relaxed. He became gradually weaker in every respect, and then sought admission into the hospital. At this time he had constant nausea; frequent vomiting every two or three hours, and always after taking food. The abdomen was tense, but not tympanitic. There was a swelling in the right inguinal canal, but no hernia could be detected. Two days after his admission, as the symptoms were not relieved, Mr. Birkett cut down upon the old hernial sac; but no intestine was found in it. The symptoms became gradually more distressing, and the patient died about four days after admission. The right flexure of the colon was constricted, as if a string had been tied round it. ' Within this constricted part, a growth was seen attached to the anterior wall of the bowel; and was of the nature described by Rokitsky as "villous cancer."'

Malignant, or cancerous deposit, productive of stricture of the intestine, though usually found to affect persons past the meridian of life, may occasionally be met with in youth.

A boy, aged 15, was the subject of a stricture of the rectum from three to four inches from the orifice of the bowel. The stricture was very tight, and accompanied by ulceration of the mucous membrane. The stricture was caused by the deposit of medullary cancer external to the muscular fibres of the gut. The patient died of acute peritonitis.

The author performed colotomy in the left loin in a gentleman, under 30 years of age, for obstruction of bowels caused by extensive cancerous deposit in and around the walls of the rectum, with considerable contraction of the gut. The patient was greatly relieved for some weeks by the operation. He then became the subject of ascites, and for this was tapped several times. After the fourth tapping he sank rapidly. On examination after death, extensive and general deposit of cancerous tubercles were found in the sub-serous tissue of the visceral, as also of the parietal peritonæum in addition to the extensive cancerous deposit in the walls of the rectum.

Advanced age generally appropriates to itself those forms of intestinal obstructions which take their origin in cancerous deposits. From the pylorus to the ileo-cæcal valve, from the cæcum to the rectum, there is no portion invulnerable to their attacks. Occasionally they are found to affect the duodenum; somewhat oftener the jejunum and ileum; most commonly the lower portions of the large intestine. If medullary stricture be found in youth, the rectum is almost invariably the seat of the mischief.

Spasmodic strictures, as they are termed, appear to depend on disordered or costive bowels, and need no comment here.

The symptoms attendant on obstruction from other causes will vary according to the completeness of the strangulation, or block.

In twists of the large bowel; simple stricture, or cancerous contractions; foreign bodies; loaded intestine. abscess of abdomen; and other chronic causes of impediment, the symptoms may vary to some extent, and in most of these instances may present themselves less suddenly.

Constipation, more or less difficulty in defæcation, small long thin or flattened motions occasionally interrupted by passage of loose evacuations, some blood, mucus, or even pus, constitute the primary and alarming symptoms of commencing stricture of the large bowel. The belly becomes distended by degrees, as the obstruction increases; pain follows upon the increase of contents; often transient periods of diarrhoea occur. The commencement of vomiting depends somewhat on the position of the obstruction. If in the upper portion of the intestinal canal, it will occur early, and distension of the abdomen will be less marked. If in the lower bowel, sickness sets in late, but great accumulation may occur in the large gut, and the peritoneal coat be in consequence ruptured before death, unless timely relief be afforded.

The examination of the general surface of the abdomen does not often convey

¹ *Path. Trans.* vol. iv. p. 154. The preparation is illustrated by an excellent engraving in the *Transactions*.

² *Ibid.* vol. i. p. 67.

much, if any, idea of the exact seat of the obstruction, unless it be caused by a tumour in that cavity. Occasionally, with a twist of the sigmoid flexure, the chief swelling has been observed on the left of the umbilicus; but very little dependence can be placed on such evidence as a solution of the exact cause or seat of the obstruction. The examination of the rectum often conveys more satisfactory information. The obstruction may be frequently here detected by the finger, or bougie; water thrown up may be immediately returned, or a small quantity may be retained, sufficient to indicate that a stricture, not to be detected by the finger, exists higher up.

A long tube passed up the rectum may enable us to detect the actual obstruction; but it is often apt to deceive us as to the seat of the stricture. 'It is, however, desirable, in all cases of obstruction, to attempt its introduction as far as possible without any force, and to inject warm water frequently and plentifully as long as faecal discharge accompanies the return of the injected fluid.

The emaciation which usually accompanies cancerous deposits in other parts, the existence of faecal fistulae in the abdominal wall, the bladder, or the vagina, are symptoms and conditions of occasional occurrence in cancerous stricture. But as in the larger majority the disease is of the epitheliomatous character, the local effects are more frequently and immediately the cause of death than the constitutional contamination, or secondary infection. Hepatic pains of previous years, or months, the symptoms of former mischief about the gall-bladder, point towards the supposition that a biliary calculus may have ulcerated into the duodenum, and produced the obstruction by blocking up the canal. Concretions, the offspring of particular kinds of food, the stones of fruit, or substances swallowed under peculiar conditions of hysteria or mania, produce similar symptoms of obstruction.

The treatment of obstruction of the bowels is a question of the deepest interest. There is too frequently a hopeless condition when the surgeon is called in. Death occurs often so early in the scene, even in a constitution otherwise healthy, that not unfrequently the medical attendant has little time to propose, or the patient to acquiesce, in measures which may prolong life; it becomes therefore a matter of grave importance to decide upon rules for our guidance under such perplexing circumstances.

In the early management of this class of cases, purgatives should be scrupulously avoided. This is a precaution to be adhered to most rigidly. But, as already observed, the golden rule to guide us in the treatment of cases of obstruction is that opium be administered by the mouth, and aperients only by the rectum. Every rule may have an exception; but experience has taught us that, whenever this one has been departed from, subsequent occasion for regret has arisen. Hot fomentations should be applied to the abdomen, especially if pain or tenderness exist. Enemata should be used frequently and in large quantities, especially if it be suspected that the obstruction is the result of impacted faeces.

The introduction of the long tube may be attended by some difficulty, but, if successful, secures a most efficient administration of enemata. The use of the latter may occasionally prove injurious. In a case of twist of the sigmoid flexure, the fluids injected in the usual manner were retained. Subsequent to death, it was found that a long tube could be inserted beyond the twist into the dilated bowel; but in consequence of a flap-like entrance at the commencement of the latter, the fluid introduced could not return. Enemata should consist of warm water, or oil, mixed with castor oil, but their mechanical action is of more importance than their specific properties. *

In the management of every case of supposed intestinal obstruction, every variety of solid food should be rigidly prohibited. Life should be entirely sustained by fluid nourishment.

When situated low down in the sigmoid flexure, or upper portion of the rectum, the obstruction will be more readily detected, as the accumulation in the larger bowel increases. In such conditions it is prudent, if practicable, to overcome the immediate effects of obstruction, by passing a small gum catheter through the stricture, and injecting warm water into the bowel; or by introducing the finger gently and slowly

into the gut above, to dilate slightly the contracted part. In the latter attempt much care is necessary. The passage of the finger should not be hurriedly or hastily effected. The stricture in these parts is commonly the result of some form of cancer; the parts are consequently thickened, often ulcerated, and brittle under manipulation. The duration of the disease has allowed it, probably, to implicate the whole structure of the surrounding gut, and has often involved the peritoneum in the diseased mass. As the bowel, from the load above, is pressed down far lower than its natural relations, the peritoneal reflection in consequence comes much nearer the external aperture; a sudden dilatation of the diseased bowel, a rapid thrust of the finger through the obstruction, can only be effected at the expense of some laceration of the diseased tissues.

A man was admitted into St. George's Hospital, under the care of Dr. Nairne, with constipation of some days' standing. Treatment having failed to procure any action of the bowels, the author was requested to make an examination of the state of the rectum. This was found pushed down so that the orifice was on a level with the lower edge of the nates. A stricture was readily felt, within a short distance of the anus, pressed down, however, by an immense collection of fecal matter. A small gum catheter was introduced without difficulty, and allowed the escape of some fluid feces and flatus, with great velocity. The forefinger was subsequently passed very slowly through a rather resistant contraction of the bowel, the result of large deposit around it. The man shortly had great desire to pass a motion, and a copious evacuation of fluid feces took place; but while on the close-stool, he was seized with excruciating pain, which continued for some time. He died the following morning. The intestines were greatly loaded, especially the lower bowel. In the pelvis, recent effusion of lymph and feculent extravasation were observed. A small rent in the peritoneum on the anterior face of the rectum, just above the recto-vesical fold, ran through the diseased (cancerous) mass into the cavity of the gut; a rent no doubt made in the wall of the bowel during the dilatation of the stricture by the finger. Through this rent the feces had passed into the cavity of the peritoneum.

We have now to discuss the conditions under which it is justifiable to operate in obstruction of the intestines, when all other efforts have failed to procure relief.

The duration of constipation is not *the positive* indication for such interference. Death takes place in three or four days, if perfect strangulation of the bowel has occurred from the pressure of a band of false membrane, or from intestine having slipped through some contracted aperture in the omentum or mesentery. In such a case, vomiting is the most important symptom. Vomiting is *the* symptom, which of itself indicates the absolute necessity of active interference, and the hazard of delay. In common or cancerous stricture of the rectum, constipation is not often complete or continuous, although the accumulation of feces may be great. Six weeks or two months may elapse without a motion, and without fatal results from such an occurrence. Constipation here again is not alone *the* symptom which warns the surgeon to interfere with his knife. In constipation following peritonitis the result of injury, in habitual or other accidental constipation, the bowels may remain locked up for a month, or even two, and yet ultimately yield to treatment or time, and recovery take place. Constipation in the latter instances cannot, therefore, be taken as *the* signal for the establishment of an extraneous outlet to the contents of the bowel.

But in the more acute instances of strangulation, with vomiting, pain, and distension, complete constipation must be present to justify operative interference. In the more chronic instances of obstruction, provided the distension be not very great, so long as fecal ejections can be secured in never so small a quantity, the means to encourage them must be persevered in; and operative measures should be delayed.

In the treatment of all forms of obstruction dependent on structural derangement or organic disease, medicines are of no avail. If the obstructing cause be not removed, or if the condition of the intestine be not relieved by some effective measures, the patient will surely die, and in a comparatively short time.

'Internal strangulation,' observes Rokitsansky, 'when diagnosed, most imperatively requires an operative proceeding, for the purpose of disentangling and arranging the intestines, and for the division of the strangulating structures.'¹ In one (Littre's) the abdomen has to be opened by cutting through the abdominal wall

¹ *Path. Anat.* vol. ii. p. 54.

into the peritoneal cavity. In the other (Amussat's) the intestine has to be reached by cutting down on it in the lumbar region external to the peritonæum. The alternative of cutting into the abdomen for the relief of obstruction in the small intestine, or of opening the colon in the loin for stricture of the large bowel, must always, at the best, be regarded as a choice of evils. A patient is suffering from the effects of some internal stoppage which will surely destroy life in a few days; or from a disease which, by causing obstruction, will prove fatal in the course of a few weeks; unless, in the former, the stoppage be overcome; or, in the latter, the effects of the disease be obviated for a time by an artificial outlet above the seat of stricture. But in either case the operation is not to be considered any but a serious one; especially so when it is necessary to open the peritoneal cavity. The gravity of this operation is increased in proportion to the youth of the patient; in infancy it is one attended by very great danger to life. Again, its gravity is also increased by every hour of delay permitted after the symptoms of acute strangulation or obstruction manifest themselves. In the other case there is the suffering entailed by distension, unrelieved bowels and vomiting, diminished nourishment, and last, though not least, the danger of ulceration of the mucous membrane from distension and pressure, and subsequent perforation; or from the distended state of the bowel rupture of the peritonæum, to be followed shortly by the giving way of the muscular and mucous coats. All these circumstances have to be well considered by the surgeon before he can arrive at any satisfactory conclusion as to the amount of immediate relief an operation may confer, or as to the ultimate advantage of any surgical interference. If operation be decidedly considered advisable, any delay in its execution is always an element of danger; and invariably in all cases the earlier it is had recourse to the greater the prospect of benefit.

In strictures of the rectum, sigmoid flexure, or transverse colon, the operation for relief is confined to either lumbar region, from whence the intestine may be opened, where it is uncovered by peritonæum. The advisability of this operation can generally be carefully weighed before it is necessary to perform it; for there is usually less urgency of symptoms in cases which require it than in strictures higher up; and often a period of a week or two may be permitted to elapse, provided the patient be carefully watched, before operation is absolutely requisite.

The conditions which demand it are, continued and unyielding constipation, distension of the abdomen, and commencing irritability of the stomach, or actual vomiting.

The conditions which forbid us to anticipate recovery, and therefore should negate surgical interference, are, shrunk countenance, feeble and quick pulse, cold or clammy skin, and general tenderness of the abdomen, superadded to the symptoms enumerated above.

The operation of opening the peritonæum for the examination of strangulated or obstructed intestine, and for the formation of an artificial anus in the walls of the abdomen, was first advocated and adopted by M. Littre, in modern times at least; though the abdomen had been opened by Pillore of Rouen in 1776, and an artificial anus formed in the cæcum, for cancerous obstruction of the rectum.¹ The operation of M. Littre is thus described: 'Il faudrait faire une incision au ventre, et recoudre ensemble les deux parties après les avoir rouvertes, ou du moins faire venir la partie supérieure de l'intestin à la plaie du ventre, que l'on ne refermerait jamais, et qui ferait la fonction d'anus.'²

This operation, originally proposed for the relief of imperforate anus, is that to which we can alone have recourse to relieve any form of internal strangulation, or obstruction dependent on mischief confined to the small intestine.

It is not desirable to adopt this operation in obstructions confined to the large intestine. The operation which insures the opening of the ascending or descending colon, commonly termed the operation of Amussat, is alone to be adopted in these cases.

¹ 'On Artificial Anus,' *British and Foreign Medical Review*, vol. xviii. p. 452. The author begs to acknowledge the assistance he has received from the perusal of this most able essay.

² *Hist. de l'Acad. des Sciences*, 1710, p. 36.

When obstruction is known to be situated in the rectum, or suspected in the sigmoid flexure, the descending colon must be opened; when suspected in the transverse or descending colon, the ascending colon, or *cæcum*, must be cut down upon. The exact seat of stricture may occasionally be ascertained—if in the rectum, by the introduction of a finger or a bougie; if in the sigmoid flexure, it is often made manifest by swelling, thickening, or hardness of the part. The stricture is less evident externally, when seated in other portions of the colon. It then often becomes mere speculation at which part of the bowel the obstruction is seated.

No experience will enable a surgeon to decide positively in all cases as to the exact position of the stricture. The distension of the bowel may in some cases interfere with the detection of a tumour, should one exist; fulness in the left loin, which in many cases can be taken as an indication of the distension of the descending colon, may be really due entirely to that of the small intestine forced into the lumbar space, and covering over a contracted descending colon, while the stricture may be situated in the transverse or ascending colon. Careful examination of the rectum may give nothing more than negative evidence: while fulness and distension in the left loin must not necessarily be taken to indicate distension of the descending colon. In three instances under the author's observation, the evidence was such as to justify an opinion that the seat of obstruction was in the sigmoid flexure; and consequently the descending colon was opened in each. It turned out that in two of the cases the seat of obstruction was above the aperture made in the bowel, but within reach of the finger; in the third case it subsequently proved to be in the transverse colon. In each of these cases the patient was turned over to the left side, an incision at once made in the right loin, and the ascending colon being found distended was opened and treated in the usual manner.

The chronic nature of the symptoms, and the slow accumulation of *feces*, must always point to the large bowel being the seat of mischief; but when symptoms render it doubtful whether the obstruction lie in the transverse or descending colon, the safe course is to open the ascending colon. The author has seen enormous dilatation of the ascending and part of the transverse colon follow on stricture of the left extremity of the latter portion of the large bowel; in one instance, to such an extent as almost to convey the impression that a large tumour might have been pressing on the bowel, and thus produced the obstruction; so very uncertain are the conditions in some cases with which the surgeon has to contend.

The operation of opening the colon was first advocated by Callisen,¹ but attempted by him only on the descending colon. M. Amussat modified it by extending it to the ascending colon. To him alone is due the credit of having revived the operation—an operation which had not only fallen into disuse, but was condemned as dangerous and impracticable.

The advantage of this operation is, that it enables the surgeon to expose the intestine and open it, where it is uncovered by peritonæum, and where it lies in front of the quadratus lumborum muscle, and merely separated from that muscle by cellular tissue. The situation of the external incision, on either side, is in the lumbar region, between the last rib above, the crest of the ilium below, a vertical line running from the end of the rib to the crest of the ilium in front, and the edge of the longissimus dorsi behind. The colon in this space is fixed to the abdominal wall by the reflexions of the peritonæum, and lies loosely in contact with the quadratus lumborum. The kidney is situated rather above the seat of the incision. There is no meso-colon here; and if the colon be much distended, the cellular space between the folds of peritonæum will be very conspicuous. It is at this part that the intestine should be opened.

Callisen advocated a vertical incision for this purpose in the loin; Amussat has judiciously recommended a transverse one. The advantages are thus fairly stated: 1st, that it makes the operation easier and more certain, and avoids the danger of dividing the lumbar vessels and nerves; 2nd, that it facilitates finding and opening

¹ *Systema Chir. Hodiern.* tome xi. p. 842, Hafniæ, 1817,

the intestine without wounding the peritonæum; and 3rd, it enables us to establish the artificial anus more anteriorly.¹

The incision should commence in front of the longissimus dorsi, and be carried forwards to the extent of about six inches. The integuments having been divided, the muscles are to be carefully cut through until the intestine is exposed. This is not a difficult or troublesome proceeding. The intestine, especially if loaded, presents its muscular surface in the bottom of the wound, uncovered by peritonæum. The bowel should be at once hooked up by a curved needle; two or more points should then be secured by threads to the margins of the wound, and the gut opened. Usually a gush of fluid feculent matter now takes place; ample provision should therefore be made to secure it as it flows out, to prevent the bed becoming soiled, which would be the case in a few seconds, if suitable basins be not at hand to apply to the edge of the wound.

The intestine should be allowed to empty itself gradually. The relief to the patient is often at once very considerable; but he should be steadily watched, and well supported, as faintness is very apt to follow upon the rapid evacuation of the long-distended bowel; or should peritonitis have set in prior to the operation, the patient will soon sink. Should he survive the operation, the treatment of the wound is of next importance. In the first instance much inconvenience and even some distress may be experienced from prolapse of the gut through the artificial opening; especially if the latter be a free one. But as the wound in the integuments has a natural tendency to contract as time advances, and the margins of the intestinal opening become adherent to the former, the prolapse will gradually diminish in proportion to the contraction, and will usually cease ultimately when the orifice becomes fully contracted. Indeed, should the patient's life be prolonged, it will be found as a rule that the surgeon's attention must be directed towards maintaining the freedom of the artificial opening sufficiently to insure the escape of the contents of the bowel. In the first instance the escape of fecal matter through the wound may be controlled by the use of an ivory ball or plug attached to a small shield, on which a piece of india-rubber sheeting may be placed, and fixed in its position by a bandage. As the wound continues to contract, it will be found best to substitute for the ivory plug a piece of sponge-tent: this may be introduced and worn in the opening day and night, but changed morning and evening. Its use has been found to effectually control the escape of air and fecal matter.

Sometimes the patient will experience discomfort from the accumulation of feces between the strictured portion of the bowel and the artificial opening; or from the contents of the bowels becoming too solid to pass freely through the aperture, and therefore care must be taken to regulate the action of the bowels with gentle aperients as circumstances indicate.

The operation of opening the colon in the lumbar region is an important measure, not only for the prolongation of life in cases of total obstruction from stricture of the rectum; but also for the mitigation of suffering in cases of ulceration and stricture of the rectum without actual obstruction. In such cases excruciating pain is often experienced when the bowels act, from the passage of fecal matter over the ulcerated surface; and it has been found that, by establishing an artificial opening above the seat of disease, and thus diverting the passage of feces, and leaving the stricture at rest, great comfort has been conferred upon the sufferer.

Mr. Curling was the first to advocate this operation under such circumstances, and he has frequently adopted it with much relief to the patient's sufferings while life lasted. He recommends previous to the operation that the bowel should be injected with fluid in order to distend it to some extent, as when in a distended condition the bowel is more readily detected and secured than when empty and contracted.

Mr. Holmes² has published the particulars of a case in which he opened the descending colon for the relief of a patient in whom there was a fistulous communication between the sigmoid flexure of the colon and the bladder. The symptoms were immediately relieved, and

¹ Amussat's *First Memoir*, p. 241.

² *Trans. Med.-Chir. Soc.* vols. xlix. and l.

the patient remained free from the passage of fecal matter into the bladder for about fifteen months, when feces again appeared in the urine. He shortly after this died, and on post-mortem examination it was found that besides the communication between the sigmoid flexure and the bladder, there had formed a more recent communication between the bladder and the cæcum.

In ten cases reported by Mr. Curling, the patients survived over periods varying from two to eighteen months. In a case under the care of the author, and in which complete obstruction had existed nearly three weeks, the patient survived the operation over two years and a half. The artificial opening had always a tendency to close, but was kept open by the use of sponge-tent.

The entire removal of a stricture of the large intestine by operation, colectomy,¹ is a subject worthy the most careful consideration of every surgeon, who may have to deal with cases of obstruction, the result of contracted bowel, due either to cicatrix or to cancerous or other growths originating in its walls.

Mr. Thomas Bryant, Surgeon to Guy's Hospital, deserves the thanks of the profession for having recently discussed this question, in an interesting communication to the Medico-Chirurgical Society in the session 1881-82. The result of a case operated on by him proved so satisfactory that we have every reason to hope his example and success may be an encouragement to others to undertake the operation, provided circumstances appear to render it justifiable or promising in its results.

To enable the reader to appreciate fully the nature of the operation adopted by Mr. Bryant, we record the particulars related by him, though in a somewhat abridged form.

A lady, æt. 50, had suffered from complete obstruction for eight weeks, and was in a very feeble state of health. The abdomen was greatly distended. The stricture could not be detected through the rectum, nor could any tumour be discovered in the abdomen after the most careful examination. Under these circumstances, Mr. Bryant decided to perform colotomy in the left side.

After the bowel was opened, the stricture was detected by the finger introduced through the opening in the colon. As the diseased portion appeared to implicate but a small extent of bowel, and not to be complicated by surrounding adhesions, or extension of growth beyond the surface of the bowel, Mr. Bryant determined to attempt its removal. He found it practicable to draw the strictured portion through the external wound, and then removed the whole mass involving the intestine: stitching each portion of the bowel, as divided, to the lips of the external wound. The stricture was of the annular kind, and involved about one inch of the bowel. It was so narrow as barely to admit the passage of a No. 8 catheter.

In the operation the edges of the upper portion of the opened intestine were carefully secured by numerous sutures to the external wound; and subsequently the lower portion dealt with in a similar manner, so that the margins of the upper and lower extremities of the divided intestine were approximated in the wound. The precautions taken prevented any escape of feculent fluid into the peritoneal cavity. The patient was greatly relieved by the operation, and steadily recovered without any unfavourable occurrence. She remained well more than six months after the operation, and reported herself to be much improved in health. The artificial opening was treated in the usual manner.

In some observations in connection with the case, Mr. Bryant observed that he considered this operation was applicable to not a few cases of stricture of the descending colon. It had suggested itself to his mind from seeing cases of localised or annular stricture of the bowel, which were free and movable, both in operations of colotomy as well as in the post-mortem room. He also very justly remarked that these annular strictures were generally local diseases, and consequently that it was desirable they should be removed where possible. He considered that the question of excision should be entertained as soon as the diagnosis of the case was made; and that in every case of colotomy for chronic obstruction of the descending colon, the possibility of being able to remove the diseased bowel should be considered before the bowel is opened. He also pointed out how desirable it was that the question of excision or of colotomy should not be postponed till the patient's powers were too feeble to bear either operation, as unfortunately is too frequently known to be the case.

Since the publication of Mr. Bryant's case of colectomy, a second has been reported by Mr. Marshall,² Surgeon to University College Hospital.

² *Lancet*, May 6, 1882, p. 721.

In the latter instance the abdomen was first opened in the median line. The diseased portion of bowel was however found towards the lower end of the descending colon, so that it could not be readily removed through the aperture in the anterior abdominal wall. An incision was subsequently made in the left loin, and the diseased mass of bowel removed through the latter opening. The open end of the upper portion of the divided intestine was then secured to the edges of the external wound by sutures; while the upper end of the lower portion of bowel 'was left projecting from the lower and hinder part of the wound, with a strong catgut ligature drawn tight upon it.' The anterior wound was closed in the usual way.

The patient was under the influence of ether for quite an hour and a quarter. She had been greatly reduced by a long illness, having shown symptoms of intestinal disturbance some nine months prior to the operation—repeated attacks of constipation, vomiting, and much colic. Her condition was, so far, unfavourable for any operation. Though she rallied for a short time, symptoms of peritonitis terminated in death on the third day. The post-mortem conditions are of interest. 'The abdomen was moderately full; the wound in the midline was united by first intention, except at the skin between the lowest two stitches; no adhesions existed between it and the intestines. There was diffuse peritonitis starting from the lumbar wound, and the hollows of the abdomen contained some thin blood-stained puriform fluid, with flakes of lymph in it. One or two coils of small intestine were adherent, by recent lymph, in the left loin; and the descending colon was similarly attached to the parts about the wound. On raising it, a small collection of pus was opened, and from the cavity containing it a finger passed easily out between the bowel and the edge of the lumbar wound; but elsewhere the union between these parts was tolerably firm. There was no sign of extravasation of feces. There was very little in the intestines; the wall of the whole colon above the line of excision was much thickened, and its mucous membrane had a uniform deep-brown colour. From this up to the œsophagus the alimentary canal was normal, no ulcer or scar could be found. The liver was small, and on its surfaces, chiefly the upper, were fourteen yellow-white new growths, most of which were covered by thickened peritonæum, containing visible vessels: most of these were distinctly umbilicated. Many other growths were scattered through the substance of the organ. They varied in size from that of a small chestnut downwards. On section they were grey-white and firm, with centres made up of spots of soft opaque yellow material. Each was surrounded by a bile-stained ring. No other secondary deposits were discovered.'

'The diseased mass, which was removed with a piece of the intestine, was about one inch and a quarter long, and so thick as to leave a channel through it only as wide as a No. 8 catheter. Its thickness was uniform all round the gut. It formed not an annular but a short cylindrical stricture. Its epitheliomatous character was undoubted. A microscopic examination of a nodule in the fresh liver showed the growth to be a columnar epithelioma.'

Although the above-recorded cases are probably the only ones in which attempts have been made to remove stricture of bowel by operation in this country, several operations have been performed on the Continent within a somewhat recent period, though not altogether with very satisfactory results.

Since the time when Littre advocated opening the intestine in the left groin for the formation of artificial anus in cases of congenital malformation or exclusion of the rectum, the attention of surgeons has more or less been drawn to the importance of endeavouring to remove, by operation, the various causes of obstruction. But the more effective method of treating strictures by removal may be said to date within the last fifty years or less. The subject is one of so much interest that we think it right to relate in a short summary the more recent results in this field of surgery.¹

In 1833, an operation for excision of an abdominal growth with part of the colon, through an incision above and parallel with the crest of the ileum, was performed by M. Reybard of Lyons. The tumour was removed with three inches of intestine; and the divided ends of the latter joined by suture. On the third day the external wound gaped; but had healed on the thirty-eighth day, and the action of the bowels had become natural. Six months after recurrence of growth commenced, and death took place ten months after the operation. There was no post-mortem examination to explain the condition of the intestine, or to account for the manner in which the restoration of the passage of feces was accomplished. Some doubt is thrown on the accuracy of the details of this case.

Another attempt was made by Gussenbauer of Liège, in 1877. He first made an incision in the median line, but, as it was not possible to remove the growth through this opening, a transverse incision was subsequently made from the above, as far back as the lumbar fascia. The tumour was partially attached to small intestine, which was torn in the endeavour to liberate the diseased portion. This mass, with about three inches of colon, was removed.

¹ We are indebted to Mr. Marshall's able communication to the *Lancet* for drawing our attention to the references here given.

Fæces escaped into the peritoneal cavity. The wound of small intestine was closed, and the ends of the divided bowel brought together by suture. The patient died in fifteen hours.

In a second case recorded by the same surgeon in 1879, an exploratory median abdominal section was completed subsequently by lumbar colotomy. The patient died on the third day. An annular cancerous stricture of sigmoid flexure, with large attached mass, in and behind rectum, was found after death.

The small intestine was opened above Poupart's ligament by Baum of Dantzig, in 1878, in a case suffering from obstruction, but in which he could not satisfy himself of an overloaded large intestine. Seven days later, the distension having been relieved, a slightly movable tumour could be felt below the right hypochondrium. The peritonæum was again laid open by a longitudinal incision over the tumour, about two and a half inches to the right of the mesial line. From this a transverse incision was afterwards made, directed towards the right side. The growth was connected with the ascending colon, near the commencement of the transverse portion. The tumour with three inches of intestine was removed. The open ends of the intestine were passed one into the other, and secured by sutures. On the seventh day severe pain commenced, and death occurred on the ninth day. The examination after death showed that the edges of the meso-colic portion of intestine had united; but the upper part was gaping, and communicated with a large cavity connected with the loose cellular tissue around the kidney, but did not communicate with the peritoneal cavity. The growth removed was of a cancerous character, and had blocked the passage of the bowel.

In another case, the abdomen was opened by Martini of Hamburg, for the removal of a tumour felt in the left side, the lower end of which could be detected in the rectum. It was found to implicate the sigmoid flexure. It was readily drawn into the wound, and removed with four inches of the intestine. It was found impossible to approximate the separated ends of bowel. The upper end was attached to the skin as in colotomy, while the lower was invaginated within itself, closed with sutures, and returned into the abdomen. No severe symptoms followed the operation; in two months the patient returned to his business.

A very interesting case is one in which two separate portions of intestine were removed by Czerny of Heidelberg, in 1880. When the peritoneal cavity was opened by anterior abdominal section, a growth was found to be connected both with a portion of transverse colon and sigmoid flexure. First a piece of the latter, two inches and three quarters long, was removed, and the divided ends stitched together; secondly, about four inches and half of the transverse colon was removed, and the divided portions brought together by suture. The operation lasted two hours and a half. The subsequent progress was satisfactory. On the eighth day fæces escaped through the wound, and continued to do so to the twenty-sixth day. On the tenth and thirteenth days copious relief took place, naturally, and daily evacuations subsequently. The external wound slowly healed, but the cicatrix soon assumed a hardened condition, and the patient died of recurrent disease, some seven months subsequent to the operation. There was extensive cancerous deposit in the course of the descending colon and sigmoid flexure, and other deposits in liver.¹

In analysing the evidence afforded by these cases, it will be observed that in three of them the sigmoid flexure was the seat of disease; in one, the descending colon was affected; in one, the ascending colon; and in one, the transverse colon and sigmoid flexure were both affected. Incision into the peritoneal cavity by anterior abdominal section was made in all of these cases; in four the divided intestine was brought together by sutures and returned into the abdomen; in one artificial anus was established, and in one the operation was ended by subsequent performance of colotomy and artificial anus.

In the cases in which the intestine was returned into the abdomen, one is reported to have lived some time after the operation, one died in fifteen hours, one on the ninth day, and one seven months after the operation, escape of fæces having occurred through the external wound subsequent to the removal of the stricture.

In the case in which an exploratory incision was made and colotomy subsequently performed, death occurred in fifteen hours. In the case in which artificial anus was at once established after abdominal section, the patient recovered sufficiently to resume his occupation for a time.

In this analysis the results of the cases published by Mr. Bryant and Mr. Marshall are not included; they are referred to hereafter.

The question which naturally arises from the experience now before us is, whether it were better, in the first instance, to have recourse to lumbar colotomy in any case of obstruction suspected to arise from disease of the large intestine, to be followed by colotomy in such cases as may appear suitable for such an operation; or whether an

¹ We beg to refer the reader to Mr. Marshall's communication for further particulars of this case. See *Lancet*, May 9, 1882.

anterior abdominal opening into the cavity of the peritonæum should be decided on for the removal of a diseased and strictured portion of intestine.

Another question also demands our serious consideration: whether it were better, subsequent to the removal of the diseased portion, that the ends of the divided bowel be fastened together by suture and returned into the abdomen; or that an artificial anus be established in the first instance, as after the operation of colotomy.

The operation itself of removing any portion of the intestinal canal must ever be regarded as a most serious undertaking. It can only be requisite in a case in which the local disease has already to some extent marked its effects on the patient; this may be, and often is, associated with cancerous deposit elsewhere; often not externally evident, frequently not suspected; and may be so surrounded by adhesions or out-growths that its removal becomes an undertaking of difficulty, and consequently of no small hazard. The operation can only be justifiable when there is a hope that in its performance the mass can be readily and entirely removed, without incurring more than the usual risks attendant on such an operation, and with a fair prospect of prolonging life.

We have already pointed out that in a considerable proportion of cases of obstruction of the larger bowel the disease is situated in the descending colon and sigmoid flexure, and that in a very large proportion of cases in advancing life the disease partakes of the nature of epithelioma.

These facts rather point to the advantages offered to the operation of colotomy in the first instance, even though only adopted as a means of investigation when our diagnosis as to the seat of obstruction is at fault.

With all the modern improvements in operative surgery it must, however, be ever accepted that abdominal section for the relief of a loaded bowel, with its surrounding complications, is a far more serious undertaking than to open the bowel in the loin. And every surgeon of experience will allow that, to open the abdomen, to remove a portion of bowel, to connect the divided ends by suture, and to return the bowel to the cavity of the abdomen, is a far more formidable and hazardous operation than to cut down on the loin, to open the bowel, if feasible to remove the cause of obstruction through the lumbar incision, and finally to establish an artificial anus.

In many cases it will be found impossible to decide at what exact spot the seat of obstruction is placed. The disease may be too high to be detected by the finger in the rectum; the abdomen may be too distended to allow of the mass being felt externally; or the diseased portion may be too small to be distinguished by touch, even were the intestine not much distended. This is no theoretical statement: it sums up the results of general clinical experience.

Taking all the evidence brought to bear on this question, it appears to us that the safest practice in a great majority of cases would be to open the colon in the loin; whether the right or the left side be selected must of course depend on the evidence in each case, as well as on the judgment of the operator. As it has often occurred to us, so it will not unfrequently happen to others, that after the bowel has been exposed in the loin, and opened, the seat of mischief has been detected by the fingers, and much more satisfactorily examined as to its surroundings, than could possibly be the case prior to the incision in the loin.

In illustration of this statement, we may mention a case in which, as soon as the bowel was opened, the stricture was detected just above the opening in the descending colon. It was so tied down that it would have been more than hazardous to have attempted its removal. Colotomy in the right loin was subsequently performed, and free escape of feces followed.

The circumstances of this case suggested to us, at the time, the possibility of removing a stricture of the colon, and the subject was subsequently discussed with some of our colleagues at St. George's Hospital, but no opportunity had since occurred to test its applicability. The particulars of the case published by Mr. Bryant offer strong positive evidence in support of the views now put forward, while the facts related by Mr. Marshall in reference to this operation we consider equally favourable to the practice suggested.

The other important question remains to be considered : how to deal with the divided bowel after the diseased portion has been removed, whether it were better to stitch the ends together and return the intestine into the abdomen, or to form an artificial anus as in simple colotomy.

The evidence appears to us to be greatly in favour of establishing ~~an~~ artificial anus, rather than to return the stitched bowel into the abdomen.

It must always be borne in mind that the above remarks apply only to treatment of stricture of the large bowel. If removal of a portion of small intestine be desirable, we cannot doubt the propriety of invaginating the upper into the lower extremity and uniting them by suture. Moreover in such a case there will not arise a doubt as to the necessity of anterior abdominal section.

In some cases, after removal of a portion of the large intestine, it may be found that the divided ends of the bowel cannot be made to approximate. In such circumstances there can be no alternative but the establishment of an artificial opening. Still another difficulty may decide the question for the surgeon. The bowel above the stricture in a case of obstruction is often greatly thickened, not unfrequently much soddened and softened, so that the walls will readily tear under the most careful manipulation, while on the other hand the lower bowel is often contracted to such an extent, that time and care may be requisite to dilate it sufficiently to accommodate the upper portion. Mr. Marshall has alluded to this difficulty. This contrast between the condition of the portions above and below the stricture must be familiar to all who have had much experience in cases of colotomy.

Let us take then the evidence before us, and what is likely to be the opinion of surgeons, as to whether the bowel should be returned into the abdomen after the divided ends have been made continuous, or whether the operation should end in the formation of an artificial anus ?

The following points placed before the practitioner may somewhat serve to guide him in his practice that in many instances the cause of obstruction is a small mass of disease confined entirely to the walls of the bowel, often without secondary complication ; that the disease in a large majority of cases is epithelial in character ; and in a considerable proportion attacks either the ascending colon or sigmoid flexure ; that the disease frequently kills, by ulceration and perforation at the seat of stricture or elsewhere, the result of pressure and distension ; and, lastly, that, when epithelioma can be completely removed, it may possibly not recur, or some time may elapse before its reappearance ;— with all these facts before us, it must be conceded, that following on colotomy, the removal of the diseased mass of bowel is not only justifiable, but should be attempted when circumstances are in favour of such operation ; the removal to be attempted first through the lumbar opening ; but should this not be practicable, then by an extension of the wound. But, by whatever external wound the diseased portion of large intestine be removed, we should decidedly prefer to complete the operation by establishing an artificial anus, than have recourse to the alternative of returning the united ends of bowel into the abdominal cavity.

When the strictured portion has been drawn towards or outside the external opening, so that the bowel can be fixed to the external opening, safety ligatures may be placed above and below the portion to be removed ; each should be tied sufficiently tight to prevent escape of contents when the diseased portion is severed from the healthy parts. The edges of the upper extremity should be attached to the margins of the external opening as soon as convenient, and for this purpose we recommend the continuous suture. If the safety ligature be not employed, the intestine may be stitched to the external opening to a very considerable extent, if not entirely, before the diseased mass is removed. Care must be taken that the contents of the bowel do not enter the peritoneal cavity. The edges of the lower extremity should be secured as near as possible to the margins of the upper extremity, and then the external wound contracted by suture as much as necessary, care being taken that the opening in the peritonæum is entirely closed. This being done, nothing remains but to treat the case simply as one of colotomy.

If the surgeon decide to bring the divided ends of the bowel together, and unite

them by suture, the upper portion should be placed within the lower, and secured by continuous suture. The entire edge of the lower bowel should be *inverted*, and so fixed by the sutures, in order to secure the contact of two serous surfaces. The ends of the suture, fastened and cut short, will in time ulcerate and fall into the bowel, should the patient recover.

ON THE REMOVAL OF THE PYLORUS FOR CANCER.

The removal of the pylorus for the relief of cancerous or simple stricture must always be considered one of the most formidable operations in surgery. In the first place, the diagnosis as to the extent of the disease must always be difficult, if not in a great measure imperfect; the structures to be dealt with are complicated by their surroundings; and the operation itself, under the most favourable circumstances, must be tedious in execution, even in the hands of the most skilful operator, and consequently exhausting to one already much reduced by partial starvation.

That the pylorus is a common seat of cancer, and that the stricture caused by the latter rapidly destroys life, by its interference with nutrition, are facts well known to all familiar with the disease. With regard to the liability of the pylorus to cancer, Rokitsansky remarks, 'the pylorus, indifferently at all parts of its circumference, is known to be the chief seat of primary fibrous and areolar cancer of the stomach.'

From this point the degeneration extends chiefly along the lesser curvature over the pyloric half of the stomach. It is singular that cancer of the pylorus is accurately bounded by the pyloric ring, and never extends to the duodenum. The scirrhus pylorus is commonly bound down by the tissues that lie behind it; but exceptions occur which require the more to be known as they materially affect the diagnosis. The degenerated pylorus may remain unattached, and will then, owing to its increase in weight, descend to the lower region of the abdomen, even down to the symphysis pubis, causing a hard, very movable tumour, which easily gives rise to mistakes.

In proportion as the parietes increase in size and thickness, the stenosis of the pyloric channel will be more or less considerable; nodose protuberances, uneven contraction of the tissues, and corrugation of the parietes, give rise to inflections presenting a more or less acute angle. The greater the stenosis, and the more the cancerous degeneration is limited to the pylorus, the more considerable will be the dilatation of the stomach, which sometimes reaches to an enormous size, and presents a more or less hypertrophied state of its muscular wall.¹ Dr. Wölfler² mentions that among 903 cases of gastric cancer, the disease started in 542 from the pylorus; but of these it was found at the post-mortem examination that in 233 there were no cancerous nodules. Still more important is the fact that in 172 instances there were no adhesions to the neighbouring organs.'

Before the surgeon can undertake, or even contemplate, the performance of the operation for removal of the pylorus, it is imperative that the diagnosis of the case should be most carefully and thoroughly considered. In the first place, to facilitate the means of arriving at a correct conclusion as regards the nature of the disease and its surrounding complications, if any exist, the patient should be placed under the influence of an anæsthetic. The tumour should be readily felt; the extent should be limited; the mass should be freely movable; and jaundice should be absent. But, with the most careful examination, although it may result that all the most desirable conditions exist, there may appear complications when the parts are exposed which would entirely defeat all attempts to remove the diseased pylorus. Indeed, it may be fairly laid down as a principle, if this operation is to be undertaken, that no one can decide on its completion until the exploratory incision has been made, and either the hand introduced into the cavity of the peritonæum to ascertain the relative conditions of the diseased mass, or it is found that the mass itself can be drawn out through the opening and more fully examined externally.

¹ *Manual of Pathological Anatomy*, vol. ii. p. 43. Published by Sydenham Society, 1849.

² See Billroth's *Clinical Surgery*. Translated by Clinton Dent, F.R.C.S., and published by New Sydenham Society, p. 404.

Let us, however, take what may be considered a favourable case for removal ; a case in which the surgeon is satisfied that the disease of the pylorus is entirely confined to the walls of the part ; without adhesions to surrounding viscera, and free from complications connected with the stomach, what are the precautions to be taken prior to the operation, and what should be the steps of the operation itself?

Billroth¹ recommends that when the mass is distinctly felt, and all external circumstances are considered so far favourable for the removal of the pylorus, that the patient is to be prepared for the operation by having the stomach washed out with tepid water several times previous to the day of its performance, and thoroughly so two hours before the operation is commenced. Should the stomach, however, be greatly dilated, it will be found a rather difficult matter to do this completely. The bowels should also be attended to the day previous, but in the class of cases under consideration the intestines are usually somewhat empty.

The steps of the operation are thus described by Billroth :—‘ An incision should be made through the abdominal wall over the situation of the tumour. If the cancerous pylorus has sunk down particularly low, it should be raised up before the incision is made.’ A transverse incision from four to five inches in length should be made over the seat of the tumour, and before the peritoneal coat is divided every bleeding point should be secured. The peritonæum is then to be opened, and the parts surrounding the diseased pylorus examined as to adhesions. He advises, if the cancer be found adherent to the pancreas, that the idea of removal should be abandoned, and the external wound closed ; so also as regards the transverse colon, or if the cancer had extended over the horizontal part of the duodenum.

‘ As soon as the condition of the parts has been made out, the stomach is drawn up to the wound, and examined to see the point at which it must be cut through ; and then to commence the removal of the pylorus with the portion of stomach and duodenum immediately adjoining.’ To begin with, the large omentum is detached from the greater curvature, and the gastro-colic ligament cut through. The layers of omentum are taken up between two clip forceps, which form grooves just suitable for the application of silk ligatures. The tissue is cut through in the middle between the ligatures ; or, still better, burnt through with the thermo-cautery. This is not, however, always necessary, for by means of blunt forceps the great omentum may be detached without any hæmorrhage ; the lesser omentum is then separated in the same way. In detaching the omentum, enlarged lymphatic glands may be met with requiring removal. During the entire operation the portion of the stomach which it is intended to replace must be covered by cloths which have been soaked for fourteen days in a five per cent. carbolic solution. When the part to be resected is completely exposed, the most disagreeable and difficult steps are over. After the stomach has been isolated, a large, flat, disinfected sponge or cloth should be laid beneath the viscus, so that the further manipulations may be carried on with ease and care. By gently lifting out the stomach as far as is necessary, all further proceedings may be conducted outside the peritoneal cavity. The sponge and cloth will prove a valuable protection if any contents left in the stomach escape when it is cut into.’

To attach the duodenum to the lesser curvature of the stomach, ‘ the tumour should be seized by the vulsellum ; the walls of the stomach are cut through with scissors, commencing at the greater curvature. After each stroke of the scissors, any bleeding points are secured ; about two-thirds must be divided. If it is found that the stomach is not completely empty, the contents should be soaked up with a sponge specially reserved for this purpose. All vessels are ligatured with fine anti-septic silk, and the cut edges of the stomach so united together that the serous coats are applied to each other.’

‘ The cancerous pylorus is now connected to the intestine alone. If there is any fear lest the duodenum should slip away when the division is completed, a few silk threads may be passed’ to secure it, and Billroth recommends a small sponge to be inserted temporarily into the duodenum.

With respect to the insertion of the duodenum into the stomach, he says, ‘ we

¹ *Op. cit.*

must begin at the posterior walls of stomach and duodenum. A very good plan of uniting them is to insert the posterior sutures before the duodenum is completely separated. In our first case the stomach was cut away, and then the upper half of the duodenum. Several threads were then carried through the walls of the stomach and duodenum to form the posterior "ring suture," and were then given to an assistant to hold while the occlusion sutures were being inserted. The posterior walls of the stomach and duodenum are to be first united by passing the sutures from within outwards to secure the contact of two serous surfaces; then the anterior portion is to be dealt with in the ordinary way.

Billroth makes some remarks about various kinds of sutures employed in this operation to connect the stomach with the duodenum; but it appears to us that the continuous suture is more applicable for this purpose than any other; it is most easily carried round the entire wound, and can be readily adapted to ensure the approximation of the edges of the wound in the most complete manner, and so retain them more perfectly than any number of uninterrupted sutures, however carefully applied. One of its great advantages is the extreme simplicity of its application, and the more rapid, as well as more complete, approximation of the edges of a long wound. If, however, a long single continuous suture were used to complete the approximation of the whole circumference of the wound, in this instance it would be apt to act slightly as a ligature round the orifice of the duodenum, and so occasion obstruction after the operation had been completed. To avoid such an occurrence, it is only necessary to knot the suture after every three or four stitches, or to use three or four separate sutures; the former is the simplest and a perfectly effectual mode of using the continuous suture; but, when used in attaching the duodenum to the stomach, it must be borne in mind that the suture has to escape through the bowel, and a very long one might be some time becoming perfectly detached, or inconveniently long to escape readily through the intestinal canal; therefore it would be well to use three or four to secure the duodenum to the stomach, one following the other. Whatever can in the least degree contribute to shorten the period of the operation, in one of such gravity, must be regarded of some importance, and certainly the continuous suture can be applied in a much shorter time than the usual number of interrupted sutures required here.

When the edges of the two cut surfaces have been adjusted and united by suture, the external wound should be treated in the usual manner.

It is remarked by Billroth, 'when all the sutures had been inserted in the first case, we were not a little astonished at the excellent shape of the new-formed stomach, which was almost normal in appearance. The greater and lesser curvatures were somewhat flattened. In our second case, therefore, we saw no reason to alter the plan of attaching the duodenum to the lesser curvature. In consequence, however, of an immense dilatation of the stomach in this case, and the greater extent of the cancer, which rendered it necessary to modify the direction in which the duodenum was divided, a diverticulum formed, as will be described presently. Profiting by this experience the following plan was adopted in the third case—the duodenum was attached to the greater curvature of the stomach, in order to guard against the formation of a diverticulum, and to provide for the more ready passage of the gastric contents.' 'Under all circumstances it is desirable to divide the stomach obliquely, in order to prevent the formation of a diverticulum.'

The diet after the operation is a point of great importance in the after-treatment. All patients, the subjects of cancer of pylorus, who submit to the operation for its removal are invariably sure to be in a greatly reduced condition prior to undergoing it, or may be at death's door from previous and long inability to take sufficient nourishment. Consequently great judgment is required in its administration. A tablespoonful of fresh milk every hour may be given during the first twenty-four hours, provided there be no vomiting, and nutrient enemata, with small doses of laudanum, should be administered every four or six hours. After the first day, if all goes well, the quantity of milk may be increased, and subsequently the fluid supple-

mented by mere solid food, should the condition of the patient permit or indicate such a change of diet.

Removal of the pylorus was first performed by Péan of Paris, in 1879. The patient died in five days. More recently the attention of surgeons has been drawn to the subject by the operations performed by Professor Billroth of Vienna, and a few other continental surgeons.

The first case operated on by Billroth was a patient, æt. 43. 'In the umbilical region could be felt a hard, easily moveable tumour, painful on pressure, and about the size of a small fist. The pyloric end of the stomach, with a portion of the duodenum, was removed. The duodenum was cut from above, and the stomach was obliquely divided. Four vessels in the stomach required ligature. All the sutures were cut short, and left in the cavity of the abdomen. The operation lasted one hour and a half. The part removed measured five and a half inches long at the lower border, and four inches along the upper border. The pyloric opening was so narrowed that a probe could with difficulty be passed through. The tumour was an alveolar colloid cancer, and a similar morbid growth was found in the lymphatic glands.'

The progress of the case was favourable. With the exception of a feeling of weight during the first twenty-four hours, the patient had no particular subjective sensations. The abdomen kept flaccid, there was no vomiting, and from the very first flatus passed abundantly. During the first day the patient had nothing but ice; on the second day, a coffee-spoonful of acid milk every hour; subsequently sweetened milk, and then gradually coffee, &c. On the twentieth day after the operation the patient was able to eat a cutlet.

'During the first twelve days the state of the bowels gave rise to some anxiety. Although the patient ate comparatively little, still large quantities of fæces were passed, but so hard were they that the nurse had sometimes to scoop them out with her fingers.' 'The motions were so white and chalk-like, that we feared that the functions of the bile were not properly discharged. As soon, however, as the patient began to take solid food, the stools (at the end of the second week) again became of a brown colour, and the fecal masses diminished in size.' Mr. Clinton Dent, the editor of the English edition of Billroth's work, reports in a note that this patient died about four months after the operation. 'The post-mortem revealed cancerous degeneration of the peritonæum, and infiltration of the retro-peritoneal lymphatic glands. The form of the stomach was similar to that of the normal organ.'

The second patient, operated on by Billroth, was 39 years of age. The operation was very similar in its details to that already described. It lasted two hours and three quarters. The pylorus was filled up by a cancerous mass, its opening just admitted the top of the finger. The growth was ulcerated on its surface, and proved to be an epithelial cancer.

The patient died on the eighth day after the operation. The morning after the operation the patient vomited; and again on the fourth day bilious vomiting took place. There was no distension; flatus passed, the wound was satisfactory. Pulse 112 to 120. 'Evidently the gastric contents did not flow into the duodenum; and evidently also there was no complete stenosis where the "ring sutures" were applied, for bile was present in the vomit. Suspecting that a quantity of fluid might have collected in the flaccid sac of the stomach, we drew off the contents, and evacuated about 200 grammes (nearly 8 ozs.) of yellowish sour fluid. Attempts were made to restore the functions by the administration of good wine and meat, but all in vain; the greater part was thrown up again in a few hours. By the next day we were restricted to giving nutrient enemata. Thinking that a diverticulum might have been left in the stomach, and that some obstruction must exist which had not been present before the operation, for the patient had never previously vomited, and had always been able to take fluid food, Professor Billroth adopted the last resource which the circumstances seemed to indicate. The wound was re-opened, and the occlusion sutures cut. The index-finger, passed into the stomach, could only with difficulty be introduced into the duodenum. The anterior ring sutures were also divided, and the wall of the duodenum attached to the abdominal walls, a drainage-tube being passed into the gut for the administration of food. The patient was very pale, and collapsed after this operation, which lasted an hour. She died on the following day.'

The post-mortem showed no general peritonitis, but only general anemia and marasmus.

In a third case, the cancer of the pylorus was found to be attached to the pancreas, and consequently the operation was rendered more tedious, as 'the isolation of the pancreas alone occupied about an hour.' The entire operation lasted two hours and a half. The patient was much collapsed during the operation; frequently retched during the afternoon, and died the same evening.

The growth removed proved to be medullary cancer. The opening of the pylorus just admitted the finger. Cancerous glands were found near the head of the pancreas, and in the lesser omentum. In addition there was old tuberculosis of the apices of the lungs, and milary tubercle on and about the pleura.

The fourth case related was operated on by Dr. Wölfler. The patient was 52 years of

age. The tumour was about the size of an apple, and freely moveable in every direction. The operation appears to have been attended by no difficulties.

'The patient was perfectly free from reaction after the operation. She had no fever, vomiting, or symptoms of peritonitis.' For the first nine days she was able to partake of meat. The operation was performed on April 8, 1881. On June 28, the patient was reported as 'perfectly well, and as able to take all kinds of nourishment without harm.' She was kept under close observation, but no trace of recurrence had, up to date, been discovered. Such are the cases and their results, as related in the work referred to. In the 'British Medical Journal,' July 1, 1882, p. 22, a case is reported to have been operated on by Professor Caselli, of the University of Genoa. The operation appears to have been performed in the manner recommended by Billroth. It occupied two hours and a half. The portion excised measured four inches and a half in length, by three and three-quarters in breadth. The patient sank from shock a few hours after removal to the ward. A post-mortem examination showed the viscera free from cancerous infiltration. The nature of the growth removed is not reported.

Professor Czerny of Heidelberg, at the Medical Congress held in London in 1881, related a case in which he had excised the pylorus—a man, æt. 28, 'who had suffered from symptoms of disease of the stomach for fifteen weeks, and who for the last ten weeks had been so reduced by vomiting, in spite of the methodical use of the stomach-pump and careful feeding, which, however, gave him temporary relief, that his weight had been reduced to ninety-four pounds. Still he was able to get about; and to this circumstance alone I attribute the good result of the operation. The stomach was enormously distended, the great curvature of which reached actually to the pubes, and contained a tumour in the neighbourhood of the pylorus, as large as a child's fist, tender to the touch, and changing its position considerably, according to the greater or lesser distension of the stomach.' An incision was made, four inches long, in the middle line; the stomach was drawn out, and an incision made into it; the entrance to the duodenum was found to be completely obstructed by hard, knobby excrescences, which seemed to confirm the diagnosis of carcinoma. The diseased mass was removed in the manner described. The operation lasted more than two hours. The mass removed proved to be cancer with small alveoli, starting from sub-mucous tissue, involving the muscular coat, but leaving the mucous membrane intact.

The wound healed without a sign of inflammation. The patient took soup on the second day, meat on the fifth, and got up on the twentieth. In the next fourteen days he gained eleven pounds in weight, and had returned to his occupation when these particulars were given.

Professor Czerny also related, on this occasion, the particulars of a case operated on by Professor Nicolaysen of Christiania. A woman, æt. 37, suffered from pain in the region of the stomach, which at last became so severe, and the vomiting so constant, that she was completely deprived of sleep. The pylorus was excised in the manner recommended by Billroth. The operation lasted two hours and a half, although no difficulties presented themselves, the tumour being freely moveable. The patient died collapsed, fifteen hours after the operation.

Professor Czerny remarked, in reference to these two cases, that he considered this operation for the removal of the pylorus as one of the most recent advances in intra-peritoneal surgery, but one which sceptics still regard with a good deal of suspicion. He considered that excision of the pylorus ought not merely to be confined to cases of cancer, but that a great future is opened up by it for those cases of simple stricture of the pylorus in which an incurable dilatation of the stomach is found, an argument already put forward by Gussenbauer and Winniwarter.

The results of the cases above alluded to have now to be examined. We find that two may be considered as complete recoveries after the operation, that the disease was removed, and life prolonged for a time, and that the patients were alive and well some few months after. Czerny one, Wölfler one. In one (Billroth) the patient recovered from the effects of the operation, but died four months after from recurrence of disease. In one (Billroth) the patient died on the eighth day. In one (Nicolaysen), in another (Caselli), and in a third (Billroth) the patient succumbed from the effects of the operation. In one (Péan) the patient died on the fifth day.¹

These facts are interesting and important, and perhaps may be considered sufficiently encouraging to justify, if not to stimulate, surgeons to undertake the removal of the pylorus when the seat of growth and stricture. The symptoms to justify the attempt should be the free mobility of the diseased portion, and the continued suffering and emaciation of the patient. It must at all times be doubtful how far the disease may affect surrounding parts; this point can only be decided by an explora-

¹ Whilst writing these pages, we see a case reported in the *Brit. Med. Journ.*, July 20, 1882, by Mr. Southam of Manchester. The patient died of shock.

tory incision. If, then, the disease be found limited to the pylorus, it would be right to attempt the removal of the mass, in the manner recommended by Billroth. The disease left to itself will surely kill, and that with much suffering, and in a short time. The operation may prove fatal, but it offers a chance of life to one who cannot long survive if no operation be undertaken, and it would be well that the patient should decide on the benefit of the doubt. The emaciated condition of patients who suffer from stricture of the pylorus is, to some extent, an advantage in the operation. There will arise no complication from superabundant fat: the walls of the abdomen will be thin; the omentum will be but a fine thin membrane. But emaciation must not be permitted to run too far. Patients suffering from any interference with nutrition rapidly fail in power, and in such conditions especially the words of Macbeth apply with trebled force as regards the operation—'if it were done, when 'tis done, then 'twere well it were done quickly.' Procrastination is dangerous when once the disease is detected and the operation considered applicable; whilst early removal offers a better prospect of success, inasmuch as the patient may be better able to withstand the shock of the operation. The operation itself has proved a long one in the hands of the most skilful; whatever will aid to shorten it will be a gain to the patient; we therefore again urge the trial of the continuous suture, rather than the use of the interrupted one, as more rapidly applied, and as thoroughly efficacious.

Mr. Lawson Tait¹ has published a case in which he removed a large impacted gall-stone from the dilated bile duct. The edges of the cyst were connected to the edges of the parietal wound by continuous suture. The patient did well. A similar operation was performed by Dr. Marion Sims in Paris, in 1878, which did not, however, prove successful. Mr. Lawson Tait² also mentions having applied the operation of abdominal section in five cases of hydatids of the liver, and in one of large cystic abscess of the same organ: all these cases recovered.

The Operation of Tapping: Paracentesis Abdominis.

When the abdomen becomes inconveniently distended with fluid, contained either in the peritoneal sac or in an ovarian cyst, it is desirable to relieve the patient by tapping the cavity in which the fluid is lodged.

Previous to the operation, the patient may be placed upright on the edge of a chair, or recumbent on the side of a bed. A broad towel, warmed, should be passed round and above the umbilicus, and a second one below; the ends of these towels should be held behind the patient, and tightened as the fluid escapes from the abdominal cavity, in order that a certain amount of support be afforded to the viscera when the whole of the fluid is abstracted. Previous to the introduction of the trocar, a catheter should be passed into the bladder and the urine drawn off. A small incision should first be made through the skin, about two or three inches below the umbilicus, just sufficient to permit the passage of the cutting surfaces of the trocar. This proceeding allows it to be passed readily into the abdomen, and with less pain than if the trocar is thrust through the integument. The trocar should be pushed nearly up to the hilt of the cannula, and the stilette then withdrawn, and care taken that the cannula does not slip out after it. The fluid will now escape freely; if serous in character, and the cavity will soon be emptied.

If the patient become faint during the flow of the fluid, a finger may be applied to the orifice of the cannula to arrest the escape, while some stimulant is administered, and until faintness passes off. The common trocar, with short cannula, is the simplest implement to use in this operation, and as efficacious as any; but of late a tube of india-rubber has been adapted to the cannula, so that the fluid may be carried to a basin at the foot of the chair or bed which supports the patient.

It sometimes happens that, after a certain quantity of fluid has escaped, the flow suddenly ceases, while there is still much remaining in the cavity; this is occasioned, probably, by intestine or some other substance coming in contact with the inner

¹ *Med.-Chir. Trans.* 1880.

² *Transactions of Medical Congress*, 1881, vol. ii. p. 229.

extremity of the cannula ; the obstruction may be remedied by either moving the position of the cannula, or introducing a blunt-pointed but perforated tube, with which each case of trocars should be provided.

The large accumulation of fluid in the cavity of the peritonæum, or in an ovarian cyst, usually pushes the anterior abdominal wall so far forward that a considerable interval intervenes between it and the surface of the intestines ; so that when the trocar is introduced, there is little risk of wounding the bowels. This is, however, an accident which occasionally happens, and therefore it behoves the surgeon to make a very careful examination of the surface of the abdomen, before proceeding to operate ; if any tympanitic resonance be detected near the umbilicus, or below it, the operation had better be postponed or avoided. Mr. Gay exhibited at the Pathological Society a specimen of a portion of the jejunum, which had been punctured in the operation of tapping, in a case of ascites ; but the patient survived the accident, and died three months afterwards, apparently from the disease which produced the ascites.¹ The wound caused by the trocar should be dressed with lint and plaster, and a bandage applied over it, round the belly. In a few days the parts have usually healed.

GEORGE POLLOCK.

HERNIA.

PART I.

PATHOLOGY AND TREATMENT OF HERNIA IN GENERAL

AN escape of any viscus from the cavity in which it is naturally placed is termed a hernia; but the observations in this essay are exclusively restricted to protrusions of the abdominal viscera. In common language this disease is called rupture. Our object will therefore be to describe the varieties of hernia developed in the different regions of the abdomen, their pathology and treatment.

The whole subject is divided into two parts.

The first embraces general considerations in relation to the statistics, pathology, and treatment of the disease.

The second is devoted to an examination of the special regional varieties of hernia, their anatomical characteristics, etiology, diagnosis, prognosis, and the treatment especially adapted to each kind.

Sex.—Both sexes are afflicted with hernial protrusions. After carefully considering the statements of writers in relation to the numerical proportion in which the two sexes are subject to hernia, we must admit that we have not the requisite data to enable us to arrive at any satisfactory conclusion. We may, however, broadly state the fact that hernia occurs more frequently in males than females. Out of a gross total of 96,886 applicants for trusses at the City of London Truss Society, the males were 78,394, the females 18,492. After a careful consideration of all the circumstances, Mr. Kingdon estimates the proportion at two males to one female, for all ages and including every variety of hernia.¹

Frequency of hernia at different ages.—The only trustworthy facts relating to the various ages at which hernial protrusions are first developed have been collected by Mr. Kingdon. In the reports of the City of London Truss Society for the years 1860 and 1861, he has tabulated 9,296 cases of inguinal and femoral hernia. All these patients passed under his personal examination, and the respective age of each individual when the hernia developed itself was ascertained as accurately as possible, by reckoning back to the age at which it was first noticed. Observers have been before this occupied in attempts to ascertain the ages when protrusions most frequently occur; but they have uniformly noted the ages of the persons at the time of their appearance before them. Accurate data were, under these conditions, never obtained; that is, if a knowledge of the age at which hernia is developed is to be regarded as a desideratum. Hence M. Malgaigne makes it appear that there are fewer cases of hernia before thirty-five years of age than after. This is a fundamental error, unless national peculiarities produce different results. The truth is, taking all varieties of hernia in both sexes, that the majority of cases are developed before thirty-five years of age.² I believe in the correctness of this fact, after having

¹ The proportion between males and females varies considerably at different periods of life, on account of causes connected with certain congenital malformations, which will be spoken of in treating of the special forms of hernia. Thus, in Mr. Kingdon's statistics for 1860 and 1861, there were in the first five years of life, 1,409 males, and only 107 females; while in the five years from 25 to 30 years of age, the proportion had changed to 846 males against 207 females.

² The following statements show the number of cases of hernia occurring at different ages, when the age of each patient was recorded by M. Malgaigne, at the time each one came

tested its accuracy as far as my means allow. It is, I know, directly in opposition to the received dogmas; but as we proceed we shall be able to assign very good reasons why hernia is so much more common before middle life than after that period.

Frequency of hernia in relation to population.—We have no trustworthy data on this subject. The general statements which have been advanced, in some of which the proportion is put as high as one in eight of the male inhabitants of the whole kingdom, and even one in five of the whole population of one district, do not rest on any precise information, and appear exaggerated.

Frequency of hernia in relation to age.—Mr. Kingdon's statistics (Table A) show that, out of 9,296 applicants for trusses, 1,516 were under five years of age. This would appear at first sight to show a much greater prevalence of hernia in infancy than during any other period of life. But this disproportion vanishes when we take into consideration the number of infants out of any given population. Thus, if we take Mr. Kingdon's table as giving an accurate idea of the numerical prevalence of hernia at different ages in London, we must compare the ratio between the number

of cases of hernia at any given age and the total number of cases of hernia, with the ratio between the number of the population living at that age and the total population. Proceeding in this manner, we shall find that, while there is no exact proportion maintained, yet the frequency of hernia slightly advances towards the latter end of life. Thus, taking the census of 1851, the total population of London of both sexes at all ages was 2,362,236, out of these, 293,562 were under 5 years of age a ratio of 1 to 8.004. Out of the 9,296 which form Mr. Kingdon's total, 1,516 were under 5 years of age: a ratio of 1 to 6.13. Taking the next decade, we find the total number of the population between 5 and 10 to be 243,648, or in a ratio of 1 to

under his observation; and when the respective ages were carefully ascertained by Mr. Kingdon, to show when the hernia was first noticed. Out of 2,343 cases recorded by M. Malgaigne (*L'Union médicale*, 1854, p. 53), 555, or 23.6 per cent., were under 35 years of age; 1,788, or 76.4 per cent., above that age. On the contrary, out of 9,296 cases recorded by Mr. Kingdon, 5,650, or 60.8 per cent., had commenced before 35 years of age; and 3,637, or 39.2 per cent., after that age.

As the two tables exhibit such different results, I wrote to M. Malgaigne, who kindly returned the following polite reply

'Mon cher confrère, — Je réponde à votre question: — les âges marqués à la page 53 (de *L'Union méd.* vol. viii. 1854) sont ceux des malades au moment où ils venaient à la visite du bureau central.'

9·69 to the total population ; the number of cases of hernia, however, is only 248, or in the ratio of 1 to 37·08 to the total number of cases of hernia. Again, it was shown above that the absolute number of cases of hernia developed under 35 years of age was greater than that of those developed above that age, the proportion in Mr. Kingdon's table being 61 to 39. But in the census table, the proportion of persons alive under 35 to those above that age is still higher, viz. 69 to 31. Therefore hernia is more common relatively to the number of the population above the age of 35 than under that age. It appears from calculation on these data, that 41 per cent. of cases of hernia are developed under the age of 35, and 59 per cent. over it.

The relative proportions of the different kinds of hernia at various ages and in both sexes, together with explanations of their occurrence, based upon anatomical and physiological facts, will be found in other parts of this essay.

The influence of occupations on the formation of hernia.—All persons, in every station of life, are liable to hernia. By far the majority of cases occur among the labouring class, which, abounding as it does in all large towns, affords a favourable opportunity to ascertain whether the pursuit of any particular trade or occupation involves a greater liability to hernia than another.

Mr. Kingdon has inquired into this subject with his usual care, and the results of the investigation are printed in the Report of the City of London Truss Society.¹ He has produced a table in order to compare the twenty-five largest classes of occupation, arranged in the order of their magnitude from the census of 1851, with the numbers of each class who applied to the Society during three successive years. This 'indicates that the patients who seek relief on account of hernia bear a direct proportion to the numerical magnitude of the classes to which they respectively belong, and not to the severity of the toil.'

The influence of hereditary conformation predisposing to the development of hernia.—A disposition to hernia may be inherited ; that is, the children of ruptured parents are frequently afflicted in like manner. Mr. Kingdon has taken great pains to ascertain the proportion of cases in which this hereditary influence exists. In the reports of the City of London Truss Society for 1860-61, he has published the result of his inquiries. Both sexes show an equal tendency to be thus influenced. The proportion, by calculation, seems to be about 34 per cent. This hereditary predisposition, paternal, maternal, or on both sides, is manifested in the most marked degree with infants under one year ; the cases being about 12 per cent. of the whole number in the first twelve months of life.

This fact points to two very important causes which give rise to hernial protrusions at this early age ; first, to the arrested efforts of nature in closing the ventral orifice of the vaginal process of the peritoneum, and the obliteration of that sheath ; and, secondly, to an abnormal elongation of the mesentery. These two structural conditions belong to a class of anomalies very likely to be determined by hereditary influences.

Congenital defects of the parietes of the abdomen have been already mentioned as predisposing causes of hernia, and this subject will be further dwelt upon in discussing its various forms. Wounds, inflammatory lesions of the abdominal walls, and other predisposing causes may be mentioned. It is a question whether a portion of small intestine can reach the fundus of the scrotum, unless its mesenteric ligament be of preternatural length. For it is difficult to understand how the upper portion of the small intestine or the cæcum can descend so low as they are sometimes seen, without at the same time their mesenteric folds being elongated. But the fact to be accurately ascertained is whether the mesentery is abnormally long antecedent to the descent of the hernia ; whether, in truth, a morbid elongation of the mesentery be a primary cause of hernia or not. Doubtless this structure becomes lengthened and stretched as the result of repeated or continued descents of the intestine ; but we

¹ Report, 1861, p. 11.

are not cognisant of any facts to prove a congenital condition of the kind above alluded to. At first sight, this circumstance regarding the elongation of the mesentery may seem to have very slight practical value. Upon reflection, however, we shall arrive at an opposite conclusion. It has a very important bearing on the question of the radical cure of hernia, as it is termed. For if it be proved that the primary cause of any viscus protruding from the abdominal cavity can be traced to a morbid condition of its peritoneal retaining ligaments, the mere obliteration of the hernial sac can avail but little in producing the intended result of affording permanent immunity from the disease. That, which often happens when a truss is used to support one kind of hernia would occur in this case also—namely, the development of another, perhaps even on the opposite side of the body; and thus any operation, even if successful in obliterating the first sac, would be of little value.

Persons in whom a hernial sac exists certainly state that they are more troubled with the descent of a hernia if they get out of health. This circumstance leads to the inference, that when the tissues generally are weakened and relaxed by indisposition, those which should maintain the viscus in its proper situation participate in the general morbid condition, and then permit the hernia to escape more readily.

It is equally certain, too, that persons constitutionally of a weak frame of body, whose contractile and fibrous tissues are deficient in tone and power, become more commonly subject to the development of a hernial sac as age advances, than those of an opposite conformation; always, of course, excepting those persons who have a congenitally open vaginal process of the peritonæum.

And further we may state, as the result of actual observation, that in both males and females of middle age the subject of hernia, the heavy abdominal viscera, the solid glands for example, are usually disposed in a much lower situation than their normal one; that, in fact, the abdominal viscera generally are not so firmly held in their proper places by their peritoneal ligaments as when no disposition to hernia is shown.

Between the muscular walls of the abdomen and the contents of that cavity a constant antagonism exists. The gaseous and fluid distension of the intestinal tube exerts an ever variable pressure against the abdominal walls, whilst they, in their turn, react upon the inflated viscera; thus between these opposing forces a sort of equilibrium is maintained. The balance between them is, however, sometimes destroyed, and the parietes are no longer able to restrain the viscera within their normal limits. Thus hernia is often associated with a great increase in the bulk of the viscera, from the rapid development of fat in the omentum and mesentery. A persistent laxity of the parietal peritonæum likewise, subsequent to distension of that membrane, occasioned by the gravid uterus, is a morbid condition which renders it liable to pass readily out of the abdomen, under the influence of any pressure from within, through the weak points of the walls, and it must also be reckoned among the predisposing causes of hernia.

The immediate cause of a hernia is certainly, in some cases, to be traced to a sudden and forcible diminution in the capacity of the abdominal cavity, the result of compression or contraction of its walls; in other words, the combined actions of the abdominal muscles, coincident with strained attitudes and postures of the body during the effort of violent muscular exertion generally, give rise to the sudden development of a hernia. We cannot, perhaps, accept as truth the statement of all the ruptured men who attribute their affliction to muscular exertion; but all surgeons who have had much hospital experience will be able to call to mind cases depending upon this cause.

A large proportion of the cases of hernia are undoubtedly of gradual development. In many of these, however, violent muscular contraction doubtless plays an active part. How often we observe hernial tumours in patients afflicted with dysuria! Is not hernia very liable to occur in persons labouring under bronchitis of one form or another? And, although it must be admitted that more or less laxity and loss of restraining power in the tissues of these persons exist with regard both to the fibrous walls of the abdomen and the peritoneal ligaments of the viscera, yet this effective

agent, muscular contraction, exerts its powers with less restraint and limit, and thus presses the viscera away from their normal situation.

The *hernia* consists of a part only of any of the abdominal viscera. Such of them as are permitted, by their peritoneal attachments, to change their relative situation within the abdominal cavity with the greatest freedom, most frequently escape or protrude through its walls. Thus portions of the small intestines and omentum form the contents of the hernial sac in the majority of cases, although a part of every abdominal viscus has been occasionally found therein.

Semeiology.—The signs which denote a rupture are more or less marked according to its volume, its condition, the viscus composing it, and the thickness of the tissues by which it is covered. The patient complains of 'a weakness' in the region in which a hernia commonly occurs: and this is often the first symptom which indicates a tendency to a protrusion in the adult. The inguinal region, especially in a male adult who makes a complaint of this kind, shows a remarkable fulness at the site of the internal abdominal ring, and often along the whole track of the region of the abdominal walls termed the inguinal canal, if carefully examined. From a similar appearance, a tendency to hernia may be detected in the weakly and delicate adult female at the crural aperture. In both cases the fulness becomes much more distinct if the patient maintains the erect posture and forcibly contracts the abdominal muscles.

Next, a small swelling or 'lump' is felt at the external abdominal ring, which is not permanent, but disappears under slight pressure or on assuming the recumbent posture. It reappears when the pressure is removed or on standing erect, and it becomes more prominent when the abdominal muscles are put into strong action by coughing or some voluntary effort.

In infants and children the tumour produced by a hernia is often of considerable size when noticed for the first time; but it soon diminishes if the swelling be pressed, or the recumbent posture imposed. In youthful adults also a hernia is often developed suddenly, generally in the inguinal region or scrotum. This, happening under the influence of violent muscular exertion or forcible compression of the abdominal walls, is usually attended with more or less pain.¹

The structure of the viscus which forms the hernia also modifies its signs and indications: thus, if the protrusion be solid, as when omentum escapes (epiplocele), the hernial swelling will be hard, resisting, and lobulated; if the protrusion be hollow, as in hernia of intestine (enterocele), the swelling will be yielding, soft, elastic; and if the contents be gaseous and fluid, it will yield a dull sound on gentle percussion, or a peculiar gurgling is heard at the time the rupture is handled.

Some swellings formed in those regions where hernial protrusions commonly occur closely resemble that disease; but as they are liable to simulate some special kind of hernia, their differential diagnosis is given in other parts of this essay.

Prognosis.—By ordinary care and precaution, a person the subject of hernia is not in great danger of those accidents affecting it which imperil life. On the contrary, however, by neglecting to employ a bandage to prevent the escape of the hernia, or by making use of an instrument which fails to effect the purpose intended—namely, the complete retention of the hernia within the abdomen—the life of the individual is perpetually in jeopardy from the liability to inflammation or strangulation of the protruded viscus.

In proportion, then, as the palliative measures directed by the surgeon are carefully employed by the patient, the prognosis in any case of reducible hernia may be regarded as favourable or the reverse.

If the hernia be a small reducible enterocele, a truss may be used, which will prevent its descent for months, or even years. If the case be one of irreducible epiplocele, complicated with the occasional descent of small intestine, the prognosis must

¹ In a manuscript lent to me by Mr. Kingdon, he shows that, out of 796 adult males, only 48 pretended to assign any cause for the protrusion; but I find that the majority of the men in whom the inguinal hernia was suddenly developed were youthful adults.

be regarded as relatively unfavourable, in consequence of the great difficulty in preventing the entrance of the bowel at the orifice of the sac, where it may become strangulated without any premonitory symptoms.

Nomenclature of herniæ.—The varieties of abdominal herniæ are named from the period of life at which the hernial sac is formed; the region in which the protrusion takes place or exists; as well as from the viscus which composes the tumour.

When named from the viscus forming the protrusion, a hernia is styled intestinal when any portion of the alimentary canal escapes. This is also termed an enterocele.

If a portion of omentum protrude, the expression omental hernia, or epiplocele, signifies its nature.

A combination of these two is called an entero-epiplocele.

The terms gastrocele, cystocele, have been applied to protrusions of the stomach and bladder from the abdomen.

The classification of hernia according to the regions in which it occurs is given in the second part of this essay.

The essential parts of a hernial tumour.—When an anatomist dissects a tumour caused by the protrusion or escape of any viscus from the cavity or region in which is naturally contained, his observations should be especially directed to three principal objects. These are:

1. *The tissues outside the sac*, or the ordinary structures of the region in which the hernia is developed;
2. *The sac*; containing
3. *The hernia itself*, or the protruded viscera.

Under these three sections we shall describe the essential elements of a hernial tumour: first, in the condition in which they commonly exist, when the only source of trouble depends upon the mere tendency to the protrusion of the hernia; and, secondly, under those morbid conditions which affect certain parts of the sac; the contents of the sac, the real hernia; and the tissues outside the sac. Upon the judicious surgical treatment of these morbid conditions the salvation of life depends.

The inciting causes of hernia.—Protrusions of the abdominal viscera result from—

1. Wounds or lacerations of the abdominal walls;
2. The weakening or destruction of the same parts by inflammatory processes;
3. The existence at birth, and persistence afterwards, of a canal which is a prolongation of the peritonæum; and,
4. The gradual expulsion of the parietal peritoneal membrane at weak parts of the abdominal walls, forming a pouch or receptacle for portions of the viscera.

1. In this essay I am not required to describe those of the first class; such cases are mentioned under the head of INJURIES OF THE ABDOMEN.

Hernia, however, occasionally occurs in the inguinal region, as the result of the application of direct violence in its vicinity, without any wound of the integuments.

2. *The weakening or destruction of the abdominal parietes* from the effects of inflammation and its results give rise to the secondary occurrence of hernia. Thus, after the healing of abscesses in those parts, it is not very uncommon to see a hernial tumour developed at the site of the primary disease. It is important, therefore, as a prophylactic measure, to support the abdominal region by means of a suitable bandage during the healing of such abscesses, and for some time after cicatrisation.

3. *Congenital patency of the vaginal process of the peritonæum.*—We must now consider that congenital condition of the peritonæum which allows a portion of the abdominal viscera to escape from its natural cavity and occupy an abnormal position in its immediate vicinity.

Towards the close of the last century, and at the commencement of this one, anatomists were very much interested in observing the changes in the situation of the testicles during the period of fetal life. Accurate observation established the fact, that the development of the testicles commenced in the lumbar regions of the fetus in utero, and that when those organs had reached a certain stage of perfection, they

migrated from their primary locality, and, pursuing a course towards the pelvis, they at last reached the scrotum, the final point of their destination. In this progress, termed the 'descent of the testicles,' and whilst they are within the abdomen, they are placed behind the peritonæum, and partially invested by it. A prolongation from this serous membrane accompanies them into the scrotum, and receives the name of the vaginal process of the peritonæum.

Thus wrote Wrisberg in the year 1800: 'Testis semel in scrotum delapsus pluribus cingitur velamentis. Tria esse membranarum genera, quæ id præstant, Tunica vaginalis communis pro teste, epididymide et funiculo spermatico simul; Tunica vaginalis propria vasorum spermaticorum; et Tunica vaginalis similiter testis et epididymidi propria; cuilibet in arte anatomica tironi nunc cognitum est.'¹

A direct and uninterrupted communication exists between the cavity of the peritonæum and the interior of this sheath; so perfect, indeed, that the more movable abdominal viscera can pass, without impediment, from the one into the other. The line of demarcation between these cavities corresponds to, or is in relation with, that arrangement of the internal abdominal fascia termed the inguinal ring, and, adherent to the posterior surface of the vaginal process, near its inferior termination, is placed the testicle.

In early fetal life, and, in many instances, for a month or even a longer period after birth, this tubular process of the peritonæum extends into the scrotum. It lies in front of the spermatic cord and testicle: extends from the internal inguinal ring to the lowest end of that gland; and forms a membranous, cylindrical canal until it reaches the testis, when it expands into an elliptical cul-de-sac. Before birth, or soon after, this vaginal process of the peritonæum is divided into two portions—a superior and inferior. The sheath contracts near the head of the epididymis, its surfaces adhere firmly at that spot, and thus two cavities are formed. The inferior one is termed the tunica vaginalis propria testis: for it is in immediate relation with a large portion of the surface of the testicle. The superior canal, termed the tunica vaginalis propria funiculi, lies in front of the spermatic cord.

When these parts are in a normal condition, the inferior cavity or vaginal covering peculiar to the testis remains throughout life as a closed serous sac, and contains a little serum. Under similar conditions the superior canal or vaginal covering peculiar to the spermatic cord is entirely obliterated. Its superior abdominal or ventral orifice is permanently closed; and although a trace of the existence of this canal is sometimes observable in adult life, it is merely a delicate fibrous cord, the ruinæ processus vaginalis peritonei. Occasionally, although very rarely, a fine membranous canal remains throughout a long life sufficiently large to admit an ordinary-sized probe. In the account of the post-mortem examination of Sir Astley Cooper, it is stated that 'a minute serous canal, not more than a line in breadth when opened, was traced, extending from a depression at the right internal abdominal ring 'along the spermatic cord, into the cavity of the tunica vaginalis.'²

Sir Astley Cooper himself writes: 'I dissected a boy, six years of age, in whom the opening of the tunica vaginalis (vaginal process of the peritonæum) was still so large that I could pass a female catheter through it down to the testis.' And further on, in the same chapter, he relates a case of 'sudden descent of a hernia into a congenital vaginal process of the peritonæum, of the nature above described, in the person of a young man whilst in the act of lifting a sugar-cask.'³ Several instances of a similar kind have come under the observation of the author of this essay.

Of the changes which take place in the vaginal process of the peritonæum.—Several distinguished anatomists have traced the changes which occur in this serous sheath to render its obliteration perfect. Without producing a literal translation of

the writings of Seiler, I believe it will be interesting as well as useful to the reader to quote the substance of his observations.¹

When the testis has reached the bottom of the scrotum, the inguinal canal, along which the cord passes, is still very short, scarcely one and a half to two lines long. In the fourth and fifth month the internal inguinal ring lies almost directly behind the external. The inguinal canal is developed in the later months, and soon after birth it is always longer. The spermatic cord now consists of the blood-vessels, vas deferens, nerves, and the vaginal canal, at the termination of which lies the testis and the larger part of the epididymis.

After the testicle has reached the fundus of the scrotum, the obliteration of the vaginal canal proceeds from the inguinal rings downwards to the superior border of the testis, so that only the proper vaginal membrane of the testis remains, as a rudiment of the vaginal canal—the tunica vaginalis propria testis. The time at which the closure of its ventral orifice takes place and the obliteration of the canal is completed cannot be well defined. It is usually closed, at least on one side, and generally at the upper part, from the internal inguinal ring to the centre or middle of the spermatic cord, even before the whole vaginal canal has contracted, especially that portion which is embraced by the internal inguinal ring. The first stage of the obliteration of this canal commences with this process.

In the second stage, the walls of the vaginal sheath unite together entirely, as far as the superior end of the testis; or it first closes in the neighbourhood of the testis, so that the centre part still remains open.

The third stage is accomplished when the canal is partially or entirely closed. This portion of serous membrane is converted into a flat band, which afterwards becomes connective tissue, but which is rather closer and finer than the rest of the same tissue of the spermatic cord.

In the fourth stage, this stripe of connective tissue always becomes thinner, and at last entirely disappears; or there remains behind only a slight trace of it below, above, or in the centre.

State of the vaginal process of the peritonæum at birth.—In the majority of new born infants some portion of the vaginal canal still remains. In 21 Seiler found 4 in which it was open on both sides; 5 in which it was open on the right side; 4 on the left; and of these 13, 5 in which the abdominal aperture continued open on either one side or the other. In 5 of the 21 infants the canal was closed above and below, but in the centre open; in 3 the inferior part was closed, but in the upper part, from the internal abdominal ring, a portion remained wide open. Likewise, in other examinations, he found the inferior part unclosed towards the middle of the spermatic cord, or even as far as the internal abdominal ring; more rarely the centre was open, and still more rarely the upper part only.

Camper found, in 53 new born infants, 23 in which the canal was not closed on both sides; 11 in which it was open on the right side; 6 on the left.

Schreger found the following relations: in 13 new born infants, the canal was open on both sides in 8; in 6 in its centre part between the abdominal orifice and the testis; in 2 in its whole length, in which also the abdominal orifice of the right side still remained open. In the remaining 5 it was open between the abdominal fold and the testis, but only on the right side.

Paletta states that, as a rule, the complete closure of the vaginal canal takes place from the twentieth to the thirtieth day after birth.

I have ~~never~~ dissected numerous fetuses of full age, and have been surprised to find in what a large majority of them this canal continued patulous either on one side or both sides.

With a knowledge of these anatomical facts, we can readily understand how it happens that a canal or receptacle exists at birth into which a portion of the

¹ Anton Scarpa's *Neue Abhandlungen u. d. Schenkel- u. Mittelfleischbrüche*, &c., bearbeitet mit einer Anleitung zu der Zergliederung d. Leistengegend, &c. Kupfertafeln von B. W. Seiler, vol. ii. p. 374, &c. Leipzig, 1822.

intestines may enter. When this takes place, the hernia of infancy exists. It is a circumstance of very common occurrence to see an infant soon after birth with an enlargement of the scrotum, which varies in size, and sometimes disappears altogether. It attains its largest dimensions when the infant exerts its abdominal muscles; it slowly decreases and is lost sight of during repose, the recumbent posture, or in sleep. This tumour of the scrotum is due to a hernia of small intestine which escapes from the abdominal cavity into the prolongation from the great serous peritoneal membrane, known by the name of the vaginal process of the peritonæum. This serous sheath, which, from its structure, allows of considerable distension, is thus converted into a hernial sac. The attention of pathologists was first drawn to this fact by Haller in 1749. His observations were confirmed, and the nature of the disease was still further elucidated, by John Hunter and Percival Pott. Haller employed the term *hernia congenita* to express that variety in which the intestine and the testis touch each other, or are contained in the same sac; and by this name the disease has been distinguished since the date of his publication. It is, however, a most inappropriate term, inasmuch as the hernia does not exist either during intra-uterine life or at birth. A congenital imperfection, it is true, allows the descent of a hernia soon after birth; and therefore M. Malgaigne calls it the '*hernia of infancy*.' But even this term is not sufficiently definite. I prefer the designation, *hernia into the vaginal process of the peritonæum*.

1. *Of the slow and gradual development of the hernial sac.*—The peritoneal membrane is capable of very great but gradual distension. This capacity is illustrated by cases of serous dropsies and of ovarian growths. In the same manner as the whole membrane yields to the general pressure of accumulating fluid, so it dilates under the influence of local pressure into a diverticulum, or sac, until it is sufficiently capacious to contain a very large part of the alimentary canal. This condition we see in those cases of enormous double scrotal hernia, which reach sometimes even below the knees.

Every hernial sac is composed of a body, or central part, above which is the neck, and below the fundus. The mouth, orifice, abdominal or ventral aperture (*le collet* of the French), is the point of immediate communication with the cavity of the peritonæum. To the tissues forming the margins or boundaries of this opening particular attention must be directed. These constitute, by their rigidity and unyielding texture, the principal impediment to the reduction of the hernia, in most cases; and it is, therefore, this part of the sac which requires to be cut in order to replace the protruded viscus within the abdominal cavity, when the reduction cannot be effected without opening the peritoneal sac.

The development of the hernial sac.—The evolution of the slowly-formed hernial sac has been very completely traced and described by Drs. Jules Cloquet¹ and Demeaux.² I shall here quote as briefly as possible the chief facts related by the last-named pathologist.

When the peritonæum, depressed by the pressure of the abdominal viscera, traverses the walls of the abdomen, it presents, at first, the shape of a digital depression; then, of a funnel; and next, that of a finger of a glove. These forms are, however, somewhat dependent upon the region in which the hernia is developed. During this period the entrance to the hernial sac is larger than the fundus, and in these conditions a strangulation of the herniated viscus cannot take place. But when the fundus of the sac has reached those tissues which offer less resistance, it dilates, becomes rounded, and assumes a spherical shape; in this condition the entrance is more contracted than the fundus, and under these conditions strangulation may occur.

There are three periods or states in which the orifice and neck of the sac

¹ *Recherches anatomiques sur les Hernies de l'Abdomen*, 4to, Paris, 1817; and *Recherches sur les Causes et l'Anatomie des Hernies abdominales*, 4to, Paris, 1819.

² *Recherches sur l'Evolution du Sac herniaire*, 8vo, Paris, 1842.

should be examined: 1st, of their formation; 2nd, of their organisation; and 3rd, of their contraction.

The first period of formation. It is important to describe the mode of formation of the mouth of the sac, since, from certain facts, conclusions which are useful in practice may be deduced. In the formation of the hernial sac it is demonstrable that the displacement of the peritonæum is a condition of more import than the stretching of the membrane.

When the hernial sac is complete, the portion of peritonæum employed to form it may be represented by a plain membrane about three inches in diameter and ten in circumference; whilst the centre of this surface is placed at the fundus of the sac at the most dilated part, the periphery, folded and puckered like the mouth of a closed purse, would be placed on a level with the opening at the narrowest part; that is to say, at the orifice of the sac, supported by the ring or the canal which the hernia has traversed. This puckering has been described by all authors, and in the plates of Jules Cloquet and Langenbeck the fact is delineated. It is also attested by preparations in almost all pathological museums. During this first period, the orifice and neck of the sac exist only in a condition to be preserved by a fibrous or muscular ring, which prevents the dilatation of the peritonæum; if this is returned into the abdomen by any mechanical means, the puckering disappears, and the orifice of the sac is effaced. If the fibrous ring is cut, or widely dilated, the same phenomenon takes place. The solution of the problem of strangulation of the intestine by the muscular or fibrous rings rests upon the study of this stage of the disease; for, at a more advanced stage, the orifice of the sac itself acquires an organisation which sufficiently explains all the phenomena of which it is the focus.

The second period, that of organisation. We may now examine the series of phenomena which take place in the neck and orifice of a perfectly-formed hernial sac. In the first period, the puckering only exists in such a condition as to be preserved by a ring, but, at a more advanced period, the different peritoneal folds form adhesions together, in consequence of the prolonged contact of their serous surfaces, and then the mouth or orifice of the sac exists independently of other structures; it becomes a new organ, annexed to the peritonæum, and has no longer need of being supported by the ring in order to exist. From this moment the orifice has an evolution peculiar to itself; it becomes the seat of very remarkable phenomena, which may be observed at different periods, and which may now be explained.

The serous surface is not alone the seat of morbid action relating to the organisation of the orifice. In the sub-serous connective tissue changes of no less interest take place. The adipose tissue in this part diminishes, and even disappears, although the person be very fat. The connective and adipose tissues seem to be transformed into a new covering, which encloses a large quantity of blood-vessels. This rich vascularisation is often seen through the transparent peritonæum of the periphery of the herniary opening, converging from all parts towards the orifice, and afterwards radiating on the superior part of the sac, where it is insensibly lost by blending with the connective tissue.

M. Demeaux considers that the organisation of this annular induration begins in the sub-peritoneal connective tissue, and that at a certain time the peritonæum itself undergoes a change; it becomes vascular, and the two structures united together adhere closely. This induration of the internal surface of the orifice of old hernial sacs is due to an annular thickening of the peritonæum, nearly limited to the boundaries of the mouth of the sac, which is thus reduced to much less dimensions than any other part of it. Preparations demonstrating these conditions, with the exception of the vascularity, are preserved in the Museums of the Royal College of Surgeons and of the different hospitals of London.

A layer of fibres, which interlace in every direction and resemble the tissue of the dartos, is said to exist around the orifice of the sac. If these be contractile fibres, they must exert considerable influence to prevent the reduction of hernia, and may be considered as one impediment to that result. Are they not, probably, an excess

of development of the contractile fibres of the connective tissue? M. Desprez considers them to be an exaggeration of the normal state. This dartos-like layer, having contractile properties, may also play its part in producing strangulation of some varieties of hernia.

The third period is one of contraction. Most writers on hernia have remarked the constant tendency which the orifice of the sac has to contract, and even to become obliterated, as soon as the herniated organs cease to act upon it.

This process is demonstrated in the cases of adhesion of the embouchure of the sac in infants; closure of its orifice in adults; and obliteration of the sac by persistence of omentum in its cavity. This termination, the most desirable of all, does not constantly occur. A gradual contraction may take place without the obliteration being complete: it is this disposition especially which gives rise to such formidable accidents.

At this period, if the orifice be examined anatomically, it is easy to prove that it has been the seat of a new transformation. In proportion as the tissues around the orifice become thicker and contract, their vascularity diminishes; and this layer, originally resembling the dartos, shows the firmness and resistance of fibrous tissue. In the second period, the orifice, susceptible perhaps of contracting spasmodically, may also permit of slight dilatation. In the third, all dilatation becomes impossible; either the margins of the orifice resist the pressure of the viscera, or the viscus which passes through the orifice becomes strangulated.

The tissues composing this annular contraction of the mouth of the sac often become nearly as hard as cartilage; and this change especially occurs in old cases, when the hernia has not been allowed to descend for a long time; for then the boundaries of the orifice are placed in the most favourable position for the process of contraction and induration to take place. But when the hernia is not reduced, the constant pressure of the viscera dilates the mouth of the sac as well as the fibrous rings.

Of the two kinds of hernial sac.—The ‘hernial sac’ is always a prolongation of the parietal peritonæum from the abdominal cavity into the neighbouring structures. Its development and formation, however, depend upon very opposite causes. Two kinds require to be described; the intrinsic and essential distinction between them depending upon their mode of development.

1. That kind which, being congenital, is merely a serous canal or sheath, the vaginal process of the peritonæum, until a hernia takes place and escapes into it, when it becomes converted into a hernial sac. The physiological designation for it would be THE CONGENITAL HERNIAL SAC.

2. That kind which is the result of a slow and gradual process of relaxation, and is produced by a stretching, yielding, or elongation of the parietal peritonæum, before and under the pressure of the viscus itself, which constitutes the hernia. For the sake of brevity, this kind may be termed THE ACQUIRED HERNIAL SAC.

The first kind, or congenital serous canal, which may become converted into the congenital hernial sac, sometimes exists throughout life simply as a diverticulum of the peritonæum, and without a hernia entering it; but the second kind, the acquired hernial sac, cannot exist unless a viscus, almost entirely invested by peritonæum, pushes the parietal layer of that membrane before it.

In other words, the first kind of sac is peculiar to a person born with any portion of the vaginal process of the peritonæum open, and who then possesses a receptacle for the ready irruption of a hernia; and if the ventral orifice and cavity of this sheath should not become obliterated soon after birth, a rupture may occur at any subsequent period of life; but the second kind, being an acquired formation, some length of time is necessary for its production, and it cannot exist at all without the continued and effective influence of the hernia itself.

Pott, writing of the two varieties of oblique inguinal hernia, the congenital and ordinary, expresses his belief ‘that common ruptures, or those in a common sac, are generally gradually formed,—that is, they are first inguinal, and by degrees become

scrotal; but the congenital are seldom, if ever, remembered by the patient to have been in the groin only.¹

The paramount importance of a due appreciation of the physiological differences between the one kind of hernial sac and the other will be demonstrated in many points of view, but especially with regard to the surgical treatment of hernia.

The treatment of reducible hernia.—The surgical treatment of all kinds of reducible abdominal hernia is divisible into two categories:

1. The employment of palliative or prophylactic measures.
2. The adoption of some proceeding designed to effect a permanent cure.

1. *Palliative measures.*—To this class belong all contrivances which prevent the descent of the hernia. These are the recumbent posture, bandages and trusses of various descriptions. If we only judge from the class of cases observed in the hospitals, and selected from among the labouring population, we should form a very inadequate estimate of the advantage which accrues to sufferers with hernia by the employment of well-adjusted trusses. We know of adult persons in comfortable circumstances who, having no need for toil, have taken precautionary measures to prevent the recurrence of the rupture, and have consequently been free from everything of the kind for several years after. Some have even been enabled to dispense with the use of the truss entirely, after wearing it some months. It is, however, a condition of the utmost practical importance that the case be treated immediately that the disposition to the formation of rupture is detected. When the hernia enters the vaginal process of the peritonæum, and that sheath is converted into the hernial sac, we may effect a cure by attempting to call forth the processes adopted by nature to close its orifice and obliterate that canal; or, in other words, to procure adhesions of the serous surfaces of this peritoneal diverticulum.

On the other hand, in the slowly-forming hernial sac, the object in making use of a truss should be, in the first instance, to prevent the development of the peritoneal sac. This may be accomplished by applying support to those weak parts of the abdominal walls through which the parietal peritonæum is forced. When, however, the sac is once developed—and this is commonly the period at which a surgeon is consulted—measures should be immediately adopted to assist in arresting its dilatation by preventing the descent of the rupture.

The expediency of judiciously pursuing the mechanical treatment of every variety of hernia cannot be too strongly urged upon the laity by the profession. In both sexes it should be carefully conducted the moment that the slightest protrusion shows itself. Whether the hernia occur in infancy, youth, at middle age, or at later periods of life, if properly watched and judiciously supported, it usually gives but little trouble; in many cases it is even cured. But, on the contrary, if it be neglected, increase in bulk, and, sooner or later, diseased states of the rupture, often leading to the death of the individual, will almost infallibly occur.

The only exception to be made to this rule applies to those rare cases of hernia into the vaginal process of the peritonæum in which the abnormal situation of the testis interposes a practical difficulty to wearing a truss, the necessary pressure of which occasions intolerable pain by compressing that organ simultaneously. But even such cases should not be abandoned as hopeless of cure, without a reasonable attempt being first made to afford relief.

The practice of leaving cases of rupture in the hands of mere tradesmen cannot be too strongly censured. Among the poor, we constantly observe the lamentable effects of this proceeding. Ill-shaped trusses are applied; the springs being too feeble, allow the hernia to descend behind the pad, where it becomes compressed; or they are too strong, and their pressure induces absorption of the abdominal parietes, on which the pad presses. Frequently a truss suitable for supporting a femoral hernia is applied to one of the inguinal kind, and *vice versa*. That which is worth

¹ *The Chirurgical Works of P. Pott*, edit. 1808, vol. ii. p. 120.

doing at all is always worth doing well. This injunction receives strong confirmatory testimony in the treatment of ruptures by mechanical means.

Characteristics of trusses.—The requisite and essential qualities of a truss are lightness, firmness, elasticity, so that it shall retain the required form or shape, suitable adaptation to the configuration of the wearer, and sufficient strength of spring to prevent the escape of the rupture from the abdomen.

The instrument consists of a pad or cushion attached to a metallic spring, with straps, so arranged that its movement during the varied postures of the body may be restrained.

Through the kindness of Mr. J. A. Kingdon, Surgeon to the City of London Truss Society, we are enabled to give the results of his extensive experience in the employment of trusses.

He considers that the circular spring truss is the most suitable form, in the majority of cases. Bandages which are not elastic do not afford sufficient support to the hernia in every posture of the body. They are necessarily unsafe on this account, as they become lax in the stooping posture of the wearer—the position of all others in which the hernia most easily descends, because of the relaxation of the pillars of the external ring. The curve of the spring and the relative position of the pad with it should be appropriate to the configuration of the wearer. A single piece of metal should form the spring and foundation of the pad. As far as practicable, the spring of the truss should pass around the bony rim of the pelvis, fitting closely to the figure, and should lie out of the region of the glutæi muscles. For, unless it be so placed, their alternate action in progression produces a corresponding movement of the pad. If these muscles be largely developed, extending upwards to the very edge of the pelvis, the curve of the spring should be wide at the shoulder, so that its bearing or resting part may be on the base of the sacrum.

For a single pad truss the free end of the metal spring should be beaten out flat and thin, and so shaped as to cling around the opposite hip—an arrangement which materially aids in steadying the truss.

The form of the spring may be designated as after the French model or the German. The former resembles the coil of a watch-spring, and is very elastic and clinging; the latter almost exactly fits the outline of the body in its state of repose. It is almost inelastic, and very hard. The French is always pressing inwards, even when the wearer is at rest. The German scarcely presses at all when the abdomen is soft, but resists with power when any expulsive force makes the abdomen swell. In practice, the best shape for the spring is one which forms a medium between these two extremes.

The pad or cushion should be of moderate dimensions. For the adult, it should not exceed two and a half inches in length, and two inches at the widest part. Its superior edge should follow the upper line of the spring, which falls a little from the shoulder or bend, where it lies in contact with the hip. The inner surface should be directed slightly upwards, but this inclination must depend upon the prominence, or otherwise, of the abdomen, as well as, in some measure, on the anatomical relations of the pelvis to the spine. The proper shape for the cushion or pad, and the materials of which it should be constructed, may be varied to accommodate particular cases, or to accord with the views of different inventors. Generally, the wearer discovers, after a little experience, which kind of pad is most free from annoyance. That pad, however, is the best which maintains perfect and unintermitting retention of the hernia. Every pad should have attached to it two studs—one near its junction with the spring, and another at its lowest point. To the upper one the transverse strap passing from the free end of the spring is attached. The lower stud is used with the thigh-strap, which should be always worn. It is loosely fastened on to the spring of the truss near its shoulder, and should fall along the hollow beneath the buttock. In the erect posture of the wearer this strap should be moderately tight. It prevents the pad from shifting from its proper position, and should never be discarded.

These appear to be the general principles by which a surgeon is to be guided in

the selection of a truss. Particular modifications suitable for special kinds of hernia will be noticed in other places.

Of the so-called radical cure of a hernia.—It would be idle to encroach upon the limits of this essay by describing in detail every method employed to effect a cure of hernia, from the most remote periods. A mere notice of them will suffice. They were—castration; cauterisation of the orifice and neck of the sac; ligature applied around the neck of the sac; incision of the sac, and subsequent healing of the wound by granulation; excision, suture, and scarification of the sac; detaching the sac from its connections and returning it into the abdomen; immediate and forcible compression of the sac by a bandage or truss; cold douche; stimulating injections, especially tincture of iodine. Such proceedings have been long abandoned, in consequence of the fatal results which frequently attended their employment.

We must, however, add the treatment recently adopted—namely, invagination of the hernial sac. Every modification of this operation is usually designated by the name of the inventor; thus there is the method of Gerdy, of Wutzer, of Rothmund, and others.¹

The principle of this operation is expressed by the words ‘invagination of the hernial sac.’ That is to say, the fundus of the sac is pushed up into its mouth, and retained there until adhesions have formed between it and the entire circumference of the orifice. By this means it is hoped that obliteration of the ventral orifice of the sac and of its cavity may become permanently established. It is an indisputable fact, that cases of reducible inguinal hernia have been permanently cured by the performance of an operation on the plan of Wutzer. We have not, however, the data by which to establish the proportion of cures to failures; but that a considerable number of the cases operated upon did fail, is certain.

Mr. Kingdon has very kindly given me the notes of sixteen cases in which an operation for the radical cure of the rupture has been performed, either by London, provincial, or colonial surgeons. The patients applied to him for relief at the City of London Truss Society. In most of these persons, at the time they ceased to be under the observation of the operator, the rupture was ‘cured;’ for reports of some of the cases appear in the medical periodicals of the day. In some of these patients the rupture was larger than before the operation, and greater difficulty was experienced in retaining it within the abdomen. In others, a protrusion existed on both sides, the second having become developed after the operation.

Through the intervention of Dr. Hermann Weber, Physician to the German Hospital, I have received a valuable communication from Dr. Otto Weber, of Bonn, who was formerly clinical assistant to Professor Wutzer. The number of persons upon whom the Professor operated amounts to about fourteen. Between 1852 and 1856 the operation was performed but once in the ‘Klinik,’ during which time Dr. Otto Weber was clinical assistant to Wutzer. The patient was a teacher, forty years old. He quitted the hospital ‘cured,’ but the hernia returned in spite of his having worn a truss.

Wutzer is still of opinion—1. That when the operation is properly performed after his method, it is not attended with danger. 2. That he has succeeded in fixing the plug of skin with invagination of the hernial sac by inducing adhesions between its internal surface and the interior of its neck. 3. That in consequence of this, if the patient continues to wear a truss (for life), a return of the hernia may be avoided.

However, Dr. O. Weber writes that he has never seen any of the so-called ‘cured cases’ radically cured, but that—First, the plug of skin is, by degrees, entirely drawn out again; secondly, that the true herniary apertures, the external and internal rings, are not closed by the operation; and, thirdly, that an imperfect cure may be effected by means of a partial closure, by adhesion of the internal walls of the neck of the hernial sac, and thickening of the surrounding connective tissue.

¹ The most complete account, especially of the German cases, is to be found in Günther. *Lehre von den blutigen Operationen*, Lieferung 50.

The cases which Dr. O. Weber had an opportunity of examining some time after the operation, showed a slight protrusion of the intestine into the inguinal canal; and there would have been a perfect return of the hernia if trusses had not been worn. It appears that, at first, the invaginated skin becomes adherent to the inguinal canal, but without the participation of the hernial sac; that the latter probably becomes merely compressed by the invaginated skin passing by its side. In the most favourable cases the inner walls of the hernial sac may adhere together, but so loosely that they soon become separated by pressure.

The results of the examination of the bodies of persons after death, upon whom the operation had been performed, are very important. Streubel has published some. Dr. O. Weber examined the body of a man who died of pneumonia in 1856, and upon whom Wutzer operated in 1840. The hernia had returned after the operation. There was not a trace of the invaginated skin in the inguinal canal, and the peritonæum did not show any signs of previous inflammation. The hernia and its sac did not differ from the ordinary cases of the same kind.

Dr. O. Weber thinks that Wutzer's method might be perhaps modified in such a manner as to become effective. But, first, he considers it is necessary to show upon the dead body that the fundus of the hernial sac can be actually invaginated into its orifice, and not merely pushed up a certain distance before the integuments.

But, instead of describing in detail the operation of Wutzer and its modifications,¹ let us inquire, what is the object the surgeon has in contemplation when proposing to perform an operation for the radical cure of a hernia? In order to be effectual and permanent, it must, of course, produce the obliteration of the hernial sac; the closure of its ventral orifice; the strengthening of those weak parts in the walls of the abdomen through which the rupture protrudes; and to these conditions must be also added, an improved tone of the peritoneal ligaments of the viscera, by which the power they exert in retaining the viscera in their normal situation is restored. Unless the operation perfectly and completely accomplishes these ends, failure must most certainly ensue sooner or later.

Another intention which the successful issue of the operation is expected to fulfil, is to enable the sufferer to dispense with the use of a truss, and thus to be free from an intolerable incumbrance. To recommend a dangerous operation, therefore, which may prove only so far successful as to impede the descent of a hernia, but yet leaves the patient under the necessity of continuing to wear a truss to prevent a recurrence of the rupture, is surely scarcely justifiable. It is contended by the advocates for the operation that the dangers to which the patient is subjected have been too prominently set forth. This may be true. Few persons have, indeed, died from peritonitis, or other causes, in proportion to the numbers upon whom the operation has been performed. But they all were subjected to that risk, and because they happily escaped the fatal complication, that is no ground for the inference that others would do so also. The facts only show that the operation may be done without exciting peritonitis in every case.

The surgeon, in the attempt to carry out his object, proposes to produce an effect in imitation of the processes of nature during the early periods of life; for there are facts to demonstrate that the cavity of the vaginal process of the peritonæum, which is, in so many cases, an apt receptacle for any protruded viscus, may become obliterated even after a hernia has passed into it in early infancy. But where is the evidence to prove that an acquired hernial sac becomes thus obliterated by similar natural efforts? The only instances, perhaps, are those in which the orifice of the sac is plugged by adherent omentum; and such cases are very rare.

We therefore believe that we shall not err in enunciating the principle that the cases of inguinal hernia selected for the performance of all operations for the radical cure should be those in which the protruded viscus has descended into a patent vaginal process of the peritonæum, and that all other kinds should be rejected as

¹ Operations intended to effect the radical cure will be described with the treatment of the special kinds of hernia.

unsuitable; and that the more efficiently the proposed methods accomplish the ends effected by the processes of nature, the more worthy of confidence they become. Thus, allowing nature to guide our procedure, we must make it a rule to select those cases in which her efforts have failed; and, by acting as her handmaid, we may reasonably hope to arrive at a successful result.

We may conclude these observations with the following quotation from the work of Mr. Lawrence: 'The subject of an incarcerated rupture submits to an operation in order to save his life. But he whose hernia is reducible, endangers his life to get rid of an inconvenience; and the operation affords no greater prospect of entire recovery than he had without it. For after he has undergone an operation, at the hazard of life, the complaint may return; and the only protection against relapse is to wear a truss.'¹

The morbid conditions of the hernia, and impediments to its reduction.—A hernia is said to be reducible when the protruded viscera can be returned into the abdominal cavity; it is irreducible when they cannot.

The impediments to the reduction of a hernia may be classed in three groups: those produced by the tissues outside the sac; those occasioned by the sac itself; and those which exist within the sac.

There are also primary or immediate causes which render a hernia irreducible, as well as secondary. Among the first we may include all those impediments to reduction which depend upon organic conditions, and relate directly to the hernial sac; as, the muscular contraction which influences the size of the abdominal rings and the tension of the tissues around the orifice of the sac; the condition of the orifice of the sac itself; and the development within the sac of adhesions or omental sacs.

The secondary are those which are partly exclusive of the hernial tumour, and occur, as it were, accidentally, and are merely due to individual peculiarities; as, for example, the development of a thick layer of fat around the hernial tumour; its great mobility; its diminutiveness; tension of the sac from accumulation of the fluid or gaseous contents of the bowel; adherent omentum lying in front of the intestine; and some other conditions.

The morbid conditions of the hernia which give rise to more or less serious difficulties may be classed under one of the following states: 1. Permanent irreducibility. 2. Distension or inflation by fluid, gaseous, or solid contents, termed obstruction. 3. Inflammation. 4. Strangulation.

1. A hernia becomes permanently irreducible, after many years' existence, on account of its size. In most cases this condition is only attributable to neglect of the use of a truss. The largest double rupture I have seen was in a bricklayer, fifty-five years old, whose bodily health, strength, and conformation were in other respects very good. The left hernial tumour was the larger, although it had only existed about three years, whilst the right had been there twelve. The lowest border of the tumour very nearly reached to a level with the patellæ. Its circumference in the largest part measured thirty inches.

Adhesions, also, when formed between the contents of the sac, or between the sac and its contents, prevent the reduction of the protrusion.

2. Distension; choking; obstruction; rendering the hernia irreducible. This particular state or condition of a hernia is attributed to the accumulation of the solid, fluid, or gaseous contents of the alimentary canal within that portion of the bowel which constitutes the protrusion. From this cause the passage of the stercoraceous contents of the canal are arrested; the alimentary canal or tube becomes choked up with its own secretions and the egesta of the stomach, giving rise to local troubles and constitutional disturbance.

The doctrine of obstruction is of great antiquity, and for a long period that morbid condition of a hernia we now term 'strangulation' was believed to originate in this

¹ *Treatise on Ruptures*, chap. vi.

cause alone. 'During nineteen centuries,' writes M. Broca, 'the existence of an accumulation of fecal matter in the hernia had been admitted, or rather supposed; but when it was looked for, the accumulation was not to be found. Thus theory fell to the ground on the first observation.'

The local symptoms of an obstructed hernia are—pain, a flatulent state of the tumour, increase of size in comparison with its usual dimensions, more or less tension, and the absence of those more severe local conditions which characterise a strangulated bowel. By careful manipulation, the gaseous and fluid contents of an enterocele may be expressed into the contiguous part of the canal, and even solid fecal matter may be felt. During this proceeding the gurgling produced by the flatus and fluid is heard, and the movement of these is sometimes felt as they escape through that portion of the bowel lying within the orifice of the sac.

At first, the constitutional symptoms indicate functional disturbance of the alimentary canal, rather than any morbid state of the tissues of the herniated viscus. There are indications merely of a blocking-up of the tube, and nothing more. Thus, slight pyrexia and nausea, succeeded by vomiting, are the most marked features, which continue even although the large intestine below that portion in the sac has been emptied of its contents after the commencement of the attack. Unless the vomiting be very prolonged, and great depression result therefrom, as occasionally happens in very delicate or old persons, the surgeon will not fail to remark the absence of the urgent symptoms characteristic of strangulated bowel.

In most cases of obstruction the impediment is removed by those means which excite the natural peristaltic movements of the alimentary tube. The local application of warmth and moisture to allay pain; repose; the administration of aperient enemata, or even in some cases, when vomiting has not occurred, of purgatives, by the mouth, are beneficial. Abstaining, in the first instance, from manipulation of the tumour, is a point of great importance. Should the impediment to the passage of the indurated fecal matter depend upon the contraction of the orifice of the sac, the enlargement of this part becomes necessary, either by cutting its tissues or those around it. The operation must then be performed in the usual manner, and in relation to the special case.

3. *Inflammation of a hernia.*—A hernia in this state shows all the local signs, and excites the constitutional symptoms, of inflammation. The combinations of those indications which characterise the condition called strangulation do not, however, exist.

Inflammation is usually the result of external violence, and may be produced by the pressure of badly-fitting trusses. A morbid state of the whole alimentary canal, of an inflammatory type, may extend to the hernia, and in that way give rise to local trouble.

Irreducible epiploceles are more liable to be inflamed than other kinds of hernia; and a patient the subject of reducible epiplocele may have the hernia inflamed,

FIG. 150.—Hernia at the Femoral Ring of a part only of the Walls of the Bowel.

The patient, 56 years old, had been ill nine days, when the exploration of a small swelling in the site of the left femoral ring was made. She was then dying, but survived the operation forty-five hours. After death peritonitis was found, and the intestine in the pelvis was united together. * The caecal end of the bowel, the tube contracted between it and the hernia adherent to the sac; a, intestine adherent to the sac; b, peritoneal sac; c, lobules of fat outside the peritoneal sac. (Muscum Guy's Hospital, Drawing 484, Preparation 2503.)

from which cause it becomes permanently irreducible by contracting adhesions to the sac.

The local signs are—pain, increase in the bulk of the tumour, a certain degree of hardness, firmness, and elasticity when it is pressed, with more or less unevenness and irregularity of surface. The margins of the aperture through which the hernia passes do not tightly embrace the protrusion, so that, in a large hernia, the finger can be passed along the pedicle of the tumour for some distance.

The constitutional symptoms are not usually severe. In the first stages more or less pyrexia arises; and when the contents of the tube are arrested in their course, the indications of that condition become marked.

It is unnecessary to describe in detail the local and constitutional measures to be adopted. Reliance must be placed upon those in ordinary use to control and arrest the disease.

There occasionally happens a variety of hernia, first noticed by M. de Littre,¹ in which only a portion of the wall of the ileum, or a diverticulum from the bowel, becomes adherent to a very small hernial sac. By extension of inflammation to the neighbouring viscera, obstruction to the passage of the stercoraceous contents of the tube arises, and death ensues.

Fig. 159 illustrates this variety. It was drawn from a case which was under the care of the writer.

4. *Strangulation*.—A hernia is said to be strangulated when the displaced viscus is subjected to a constriction which impedes or arrests the circulation of the blood through its vessels, the passage of the stercoraceous materials along its canal, and constitutes an impediment to its return into the abdominal cavity. This condition excites constitutional symptoms of a most dangerous and characteristic nature.

Is the condition of a hernia, termed strangulation, solely the result of mechanical constriction produced by the margins of the orifice of the sac; or does it depend upon a morbid action engendered in the tissues of the protruded bowel antecedent to its escape from the abdominal cavity? In several instances of strangulated femoral hernia in women, and some cases of inguinal hernia in men, the patients themselves voluntarily stated that, for some hours before the hernia caused any inconvenience, or was even in the sac, their bowels had been 'disordered,' 'relaxed,' or that they had been suffering with 'bowel-complaint.' In other cases, there seemed to be a great tendency to a very rapid derangement of the mucous membrane along the whole track of the canal above the hernia, scarcely explicable upon the supposition that it had been all excited by the mere existence of a constriction around a small knuckle of intestine. As evidence of this morbid action, I would adduce the fact of the rapid and abundant secretion from the entire mucous surface of the small intestines, their great distension and intense vascular congestion, witnessed in some instances.

Again, given any case of reducible hernia, which for months, or even years, has readily glided into the hernial sac, and has been returned as easily into the abdominal cavity, why on some particular occasion should it become irreducible when it has passed through the same orifice it has been in the habit of traversing, and in the tissues of which no appreciable changes have occurred? For it is in vain we seek any marked alteration in the structures around or composing the orifice of the hernial sac itself.

In giving an affirmative reply to the above inquiry, we are justified by facts in attributing the strangulated state of a hernia to a predisposing cause, commencing in a morbid state of the alimentary canal generally; at least in some cases. Patients often relate how they had observed that the hernial tumour was 'larger than usual' before they suffered much inconvenience; and this circumstance is commonly attributed by them to a greater bulk of the protruding viscus. But we have no proof that this is the correct explanation of the increase of the size of the tumour in all cases; in some doubtless it may be. It is due to a distended state of the bowel rather than to quantity.

¹ 'Obs. sur une nouvelle espèce de Hernie,' *Mém. de l'Acad. royale des Sciences*, 1700, p. 300.

Let us examine a case of reducible inguino-scrotal enterocele. At one moment all that the surgeon can detect is a slight fullness produced by an empty hernial sac. At another, a small knuckle of intestine, having descended in an empty condition, becomes more or less filled with the stercoraceous contents of the alimentary canal from above it, and an elastic swelling results, which is produced by the bowel and its contents, fluid and gaseous. Assisted by the peristaltic movement of the viscus itself, or by gentle pressure, these contents of the tube are conveyed along the proper channel, and the hernia—that is, the bowel—is emptied, and it readily resumes its normal position in the abdominal cavity. Observe, now, that the tissues of the bowel have undergone no change. But let the distension continue, and the first indications of mischief are local pain and an enlargement of the swelling; next, a sensation of uneasiness in the hypogastrium, of dragging from the rupture upwards, still greater increase in the magnitude of the tumour, and great pain when handling it, take place. Do we not recognise in these phenomena the peristaltic action of the canal, the swelling of the tissues of the hernia by congestion of its vessels and irritation of its nerves? During these progressive stages the protrusion has attained a size dependent upon more than one cause. Distension caused by accumulation of its contents, and swelling of its tissues, induced by the effusion of inflammatory products, reacting against the narrow orifice of the sac, produce more or less retardation or arrestation of the sanguineous current in the blood-vessels of the rupture, and its strangulation is the result. The increased bulk of the protrusion prevents its retrograde passage through the small aperture by which it escaped from the abdomen. The body of the sac being also stretched, may mechanically contract the dimensions of its orifice in some measure; whilst the arrangement of the whole tumour, in relation to the mouth of the sac, may likewise afford an impediment to its reduction.

The filaments of the nerves of the injured bowel play an important part in transmitting thence to the nervous centres the local disturbance of their sentient extremities, and constitutional sympathies are excited. The heart contracts more frequently, and with greater force; the pulse is full, and more frequent than normal; the cheeks are flushed; the surface of the body is warmer than usual, often moist, though sometimes dry; the tongue is covered with a white fur; nausea and intolerance of food are complained of; tenesmus occurs, and flatus or a small quantity of feces may be expelled, if the large intestines chance to contain any.

Uncontrollable retching and vomiting become the next established features of the disease, prostration of the bodily powers rapidly supervenes, and death may take place at this stage from collapse alone.

Enlarging upon this brief sketch of the symptoms which indicate the commencement and progress of strangulation of intestine, we must now systematically describe—

First, the condition of the hernia when strangulated.

Secondly, the changes taking place in the tumour.

Thirdly, the constitutional symptoms excited by the local disease; and,

Fourthly, the morbid conditions developed within the abdominal cavity.

The structural changes taking place in the hernia.—When the bowel is in the condition implied by the word ‘strangulation,’ the circulation of the blood within the vessels of the part is, at first, impeded. Congestion of the capillary vessels is the consequence, and the tissues of the viscus become swollen. When exposed to view, in this first stage, the serous membrane is of a deep-red tint, and through a lens the minute blood-vessels may be distinctly seen with their outlines well defined. To the touch the hernia feels firm, and resists slight pressure; but the elasticity and resiliency of its tissues still continue unimpaired.

Next, the circulation of the blood is arrested. The tissues of the bowel, about which the constriction is tight, become now more swollen; they have palpably a solid, leathery consistence; the colour of the serous surface is a dark purple; it is dull, lacks its usual lustre, and sometimes, varying as regards shade or depth of colour, it is mottled with a red and purple tint. Patches of extravasated blood appear in

the subserous connective tissue, and an adhesiveness to the fingers is very striking.

When the bowel has been strangulated many hours, its tissues are more swollen and soft; they no longer possess their characteristic elasticity, but they remain in the same position in which the pressure of the finger places them. The serous surface has lost all its characteristics; it is black, ash-coloured, flocculent, and adhesive. In this stage all the tissues of the bowel have undergone more or less disorganisation; blood is extravasated in the connective tissues between the different coats of the viscus; the mucous membrane is soft, flocculent, and easily detached from the fibrous walls. Probably in some part of the bowel, at its convexity, or where it is in immediate relation with the mouth of the sac, its tissues have sloughed, or ulceration is concealed by shreds or patches of adherent lymph. The intestine is also firmly fixed to the mouth of the sac by inflammatory adhesions.

The last stage is that in which the entire mass of the protruding bowel has become gangrenous, or has passed into a condition termed sphacelus.

In the diseased conditions just described, we may recognise morbid changes similar to those which are observed in structures on the outside of the body. If a string be tied around the penis near the prepuce, the latter organ becomes first swollen; secondly, inflamed; thirdly, it suppurates; and lastly, it mortifies. Ulceration also takes place at the part with which the ligature is in contact.

The coats of the bowel are often ulcerated by the pressure of the constriction to which they are subjected, but the various tissues of which the viscus is composed are endowed with different powers of resistance to those morbid processes. Thus it may be seen, on cutting open the intestine, in cases in which the bowel has been deeply sulcated or grooved on its serous surface, without any trace of abrasion thereon, that the mucous membrane is ulcerated in a line corresponding to the part immediately embraced by the medium of constriction. Occasionally it happens that the line of ulceration forms only at that end of the strangulated bowel directly continuous with the upper and distended portion of the alimentary tube, whilst there is none at the other end. This is probably caused by the pressure of the distended bowel within the abdomen, and it may be seen, particularly in some cases where the knuckle of intestine lies in close relation with Gimbernat's ligament. We have even observed blood in the fecal evacuations of patients who have died with the bowel thus diseased.

Mr. Bryant states¹ that ulceration at the line of stricture is most frequently in inguinal hernia, although the sulcated condition of the bowel is as common in femoral as in inguinal; and that fecal extravasation, if not produced by ruptured bowel from taxis, generally follows ulceration at the line of stricture.

Small, recently-developed herniæ are more frequently strangulated than large ones, and those which have existed some time. Sir A. Cooper writes: 'A small hernia is more easily strangulated than a large one, the pressure on the contents being more violent, and the symptoms are much more urgent, as the stricture acts with much more effect upon a single knuckle in stopping its circulation, than when the contents of a hernia are large and voluminous.'²

It is a matter of great importance to distinguish between the two classes of hernia—'RECENT' and 'OLD.' Mr. Pott observes: 'Recent herniæ are in general more liable to stricture than old ones, for reasons which are obvious from what has already been said; but when old ones get into the same circumstances, the symptoms are much the same; though I think in general they are not altogether so pressing, and the latter generally admit of more time to attempt reduction in.'³

And Mr. Bryant has demonstrated, by the cases admitted into Guy's Hospital, that in recent hernia strangulation frequently occurs, and that the risk attending it is very great, even although the bowel be speedily liberated.⁴

⁴ *Guy's Hospital Reports*, 1861.

*Morbid states of the hernia induced by violent manual pressure.*² Let it not, however, be assumed that the morbid states of a hernia, above described, are always inevitably due to the compression which the orifice of the sac has exerted around it. Such is not the fact. The tissues of the herniated viscus are rarely so firmly constricted as to produce in a short space of time complete mortification, absolute death, of the whole of the knuckle of bowel in the sac; yet this state of the hernia is often met with. In these cases, the protruded viscus has been subject to another source of damage and destruction. Under the mild expression of 'the use of the taxis,' the hernia has been forcibly compressed by manipulation; its tissues, have been contused and irreparably damaged; blood has been extravasated in profusion between the different layers of the tissues composing the viscus, and complete disorganisation of its structures is the result of the injury inflicted. I have been for many years interested in ascertaining, from the observation of the state of the bowel after death, the comparative amount of injury inflicted on the viscus by the natural constriction of the orifice of the sac, with the tissues around it, and that produced by violent manipulation of the tumour, with the hope of reducing the hernia. I am constrained to state that the damage produced by the first cause is in no degree commensurate with that which results from the last; and that in all the instances in which the entire bulk of the herniated bowel was in a state of sphacelus, that condition was the result of violent, protracted, and ill-applied manipulation. The progress of these morbid processes is likewise accelerated by the same means, for it does not often happen that mortification of the whole piece of the bowel is observed in those cases in which the nature of the disorder happens not to have been recognised very early, and when the manipulation of the tumour has not been employed.

I may represent the danger which is associated with violent attempts to reduce the hernia, by stating, in a few words, that more irreparable damage may be inflicted on the bowel in a few minutes by coarse, careless, impetuous brute force, than the natural means of constriction could produce in several days.

Need I add, that in the attempts to reduce a strangulated hernia, the employment of such violence as must be necessary to produce these results is reprehensible in the extreme, and is justly condemned as not only opposed to every sense of humanity, but because it is in violation of all the principles of practical surgery?

Artificial anus.—Two conditions of the intestine lead to the formation of an artificial anus. One, in which a portion only of the wall of the intestine sloughs, leaving a small ulcerated opening as if a piece had been punched out, which does not interfere with the continuity of the alimentary canal, although it allows a portion of its contents to escape. This opening commonly forms at about the centre of the convex free border of the knuckle of intestine, and at a point farthest removed from the orifice of the sac.

Another variety is due to ^{an}ulceration of all the coats of the bowel, even to the mesentery. It usually occurs in the part of intestine at the mouth of the sac; and, in consequence, the continuity of the canal is destroyed, and all the stercoraceous matter escapes through the opening.

Intermediate between these two extremes we meet with varieties in which more or less of the walls of the tube is destroyed, producing corresponding results. I may state that, after the first accident, repair of the tube frequently takes place, the wound of the integuments heals perfectly, and complete recovery ensues.

After the second, however, the prognosis is not so favourable; for, commonly, an artificial anus is permanently established, and more or less of the contents of the alimentary tube are discharged thereat.

As the result of long-continued constriction by the mouth of the sac, and the pressure made upon the two pieces of intestine lying therein, their walls become adherent at the points of contact, ulceration takes place, and the continuity of the tube is thus established within the abdomen, by the processes of nature alone. This

condition is very rarely met with, and I may therefore refer the reader to a published case.¹

Figs. 160, 161 show the appearances before described.

FIG. 160.—Artificial Anus after Strangulated Ileum, at the convexity of the Tube.

The patient, 72 years old, was the subject of strangulated femoral hernia for 'two days,' but probably more, when the protrusion was returned by operation. The bowels acted freely by the anus, but on the fifth day from the operation faecal matter was discharged from the wound (*b*). Faeces continued to pass through it until death, which took place seventeen days after the operation. The perforated bowel was the ileum, about a foot from the caecum, which is seen in the woodcut (*c*). It is raised from the mouth of the femoral aperture to show it more distinctly. Local extravasation into the peritoneal cavity was prevented by adhesions between the margins of the perforation neighbouring coils of bowel and omentum (*a*, *d*). The patency or marks on the coil above and behind are the remains of those adhesions. (Drawings, Museum Guy's Hospital 486.)

FIG. 161.—Illustrates that variety of Artificial Anus in which the continuity of the tube is destroyed in consequence of destruction of the entire calibre of the bowel.

From a case of femoral hernia in a woman 67 years old. The bowel had been strangulated fifty-five hours when her niotomy was performed and the intestine reduced into the abdomen. Four days afterwards faeces escaped from the wound. Sloughing took place around the wound, and the woman lived three weeks. *a*, symphysis pubis; *b*, femur leading from the caecum; *c*, the lower end of the ileum; *d*, the lower end of the ileum; *e*, part of the abdominal wall. (Drawing, Museum Guy's Hospital, No. 486.)

Morbid conditions of the coverings of the hernia.—The changes taking place in the tumour affect the hernial sac and its coverings or investments. When they are purely the result of disease induced by strangulation of the hernia, they extend progressively from within outwards; but if produced by violence in the manipulation of

¹ *Transactions of the Pathological Society*, vol. x. p. 128; the preparation is preserved in the Museum at Guy's Hospital, No. 2402¹⁰.

the tumour, the integuments show early indications of the injury by ecchymosis, as well as inflammation of the subcutaneous connective tissues, oedema, &c.

The severity of the pain caused by handling the tumour when the hernia is strangulated differs in a remarkable manner in different individuals. In some persons the tumour becomes quickly sensitive, and even intensely painful, so that the patient is intolerant of the most gentle manipulation, especially in the region of the orifice and neck of the sac. Sometimes, in cases of acute strangulation especially, the sufferer can scarcely be induced to lie quiet in bed, but writhes about in torment praying for instant relief. Other patients, on the contrary, endure the necessary examination and even pressure of the tumour, without evincing very marked signs of pain.

At indefinite periods, after symptoms of strangulation of the intestine have appeared, the size of the tumour often increases rapidly; its surface becomes more uniform and regular; the integuments tense, smooth, shining, red, with increase of temperature; and the general outline of the whole swelling assumes a more pyriform shape, or is more locally circumscribed, according to the variety of the hernia. Fluctuation may also be detected in some cases. It must, however, be remembered that the displacement of gas by pressure upon the tumour causes a sensation very closely resembling that which indicates the presence of fluid, and that the difference between one and the other is not always perceptible even by surgeons of great experience in delicate manipulation.

The sudden enlargement of the tumour is explained by the fact of a rapid secretion and accumulation of serum within the hernial sac in numerous instances; by the distension of the enterocele with gases in others.

Characters of the serum in the sac - The serum varies in character according to the duration of the strangulation. When the sac containing a strangulated hernia is cut open, some fluid usually escapes. In colour, consistence, and odour, this serum varies considerably in different cases, and these diversities may be regarded as important indications of the condition of the tissues of the strangulated bowel.

It is pale yellow, clear and bright, when strangulation has existed a few hours only; and, under these circumstances, the intestine is simply deep red from vascular congestion, and its tissues elastic.

It is dark brown, but clear, when strangulation has existed many hours; and the intestine is then of a purple tint, but its tissues elastic.

Its colour resembles that of a strong infusion of coffee; it is turbid; blood and small coagula are mingled with it, when the protrusion has been long strangulated or protracted and violent taxis employed; now the intestine is dark purple inclining to black; its tissues are leathery, not resilient, infiltrated with blood, and often flakes of lymph are adherent to its surface.

When turbid, dull brownish yellow, and containing blood, coagula, pus, flakes of lymph, and even faecoid matter, in which state the odour of faeces is perceptible, the intestine is usually approaching a gangrenous condition, if it have not already passed into sphacelus.

The escape of gas through serum, of the nature last described, producing bubbles, is an indication that the herniated bowel is probably ruptured, and that a communication exists with the interior of the alimentary tube.

If the progress of the disease be not arrested by the liberation of the bowel, its tissues mortify, the coverings of the sac become inflamed, infiltrated with serum, and at last with pus. Crepitation may be felt, which arises either from the development of gases in the decomposing tissues, or depends upon their escape from the alimentary tube; and finally gangrene of the skin ensues, and through the opening caused by the separation of the slough the contents of the intestinal tube escape, and an artificial anus is established.¹

¹ John Hunter writes: 'It is very curious to observe in hernias, that while the gut is in the sac and alive, no inflammation takes place on the sac or integuments; but the moment the gut becomes mortified or dead, the stimulus of an extraneous body takes place imme-

In cases of entero-epiplocele, after the reduction of the intestine by the taxis, the irreducible omentum sometimes becomes inflamed, and, together with the sac and its coverings, suppurates, sloughs, and becomes detached in the usual manner; the patient subsequently making a good recovery.

Constitutional symptoms induced by the morbid state of the alimentary canal above the hernia.—Many of the general or constitutional symptoms of strangulated hernia are excited by the morbid condition of the part of the alimentary canal above the portion herniated, more than by the state of the hernia itself. The simple obstruction to the passage of the stercoraceous contents of the tube induces severe constitutional disturbance; an illustration of which is afforded by cases where the canal is crossed by fibrous bands, or directly compressed from any other local cause.

There are so many functions disturbed by the retention of the hernia in the sac, that it is very difficult to assign the constitutional symptoms to any single circumstance, such as the constriction of the hernia. Yet it is almost impossible to deny that some very marked influence arises from this single cause alone; for what change is more marked or striking than the cessation of vomiting immediately ensuing upon the liberation of the bowel? The hernia is indisputably the primary and exciting cause; but much of the constitutional disturbance must be referred to those morbid phenomena which progressively arise as the result of mere obstruction of the alimentary canal.

We may consider these effects of obstruction under two heads. First, those produced in the portion of the viscera within the abdomen; secondly, those excited in the nervous, respiratory, and vascular systems.

Effects of obstruction.—That part of the alimentary canal which is between the stomach and the hernia becomes by degrees distended with flatus and fluid of a dark brown colour. The mucous membrane is deeply injected, sometimes of the colour of blood. The serous membrane is also red, from vascular turgescence; and often patches of a deep red tint produce mottling of its surface. After long protracted distension, the contractile tissues of the small intestine seem to lose their function, which in some cases they never regain. When obstruction occurs to a part of the colon, the patient may die from perforation of the coats of that bowel, or even of the cæcum. The portion between the hernia and the anus, whether small intestine or large, is contracted; the mucous and serous membranes are generally pale. The bowel often contains a little tenacious mucus.

Results of peritonitis are seen after death in the form of shreds of plastic lymph adherent to and lying between the coils of the bowels; or a large quantity of sero-purulent effusion occupies the peritoneal cavity.

Constitutional symptoms of strangulated intestine.—The constitutional symptoms which are regarded as indicative of strangulated intestine, when associated with a local tumour in any site of a hernia, become marked and highly characteristic after vomiting has once commenced.

That train of symptoms seems to be mainly due, first, to nervous irritation starting from the herniated viscus, and afterwards to the interruption of the passage of the stercoraceous matter; for any circumstance producing mechanical obstruction causes very similar results. Thus, if any part of the alimentary tube be confined by adhesions, pressed upon by a tumour, or ligatured by a fibrous band within the abdomen, many of the results attending the accident resemble those of strangulated

diately; an outlet is then endeavouring to be made by the inflammation and suppuration of the sac forming an abscess in it; which matter, with the contents of the gut, is brought to the skin. While this is going on, the sound gut within the abdomen, where it passes into the rings, adheres to those rings all round; so that when the abscess is formed, burst, or opened, and the mortified parts sloughed off, these ends of the gut open into the abscess, and not into the cavity of the belly.—*Hunterian MS. Descrip. Cat. of the Path. Specimens in the Mus. Roy. Coll. of Surgeons of England*, vol. iii. p. 117.

hernia. Likewise somewhat similar symptoms attended ileus, enteritis, and some forms of constipation.

It is perhaps more correct to state that certain characteristic phenomena taking place in association with a tumour, at a site where it is known hernia commonly, or even rarely, occurs, would lead to the inference that a portion of bowel had become strangulated, especially if certain local indications, superadded to mere swelling, also existed.

Usually, the first symptom the patient complains of is vomiting. Upon careful inquiry, however, it is commonly stated, especially if the case be one of old hernia, that more than usual pain had been experienced at the site of the tumour; or that, for some hours before, it was observed to be larger than usual. Nevertheless, so little trouble is sometimes occasioned by the tumour, in the first instance, that patients often attribute the protrusion of the hernia to the effects of the straining in the act of vomiting. Occasionally, too, soon after rising from bed in the morning, the patient complains of nausea, which is rapidly succeeded by vomiting, without being previously aware of the existence of any hernial tumour. This is frequently the history of females, who perhaps have been toiling laboriously the day before. The same likewise happens in persons who, knowing themselves to be ruptured, and having never worn a truss, designedly conceal the fact. So little local inconvenience is sometimes caused by the hernia, that the attention of patient and medical attendant being entirely engrossed by the act of vomiting alone, both remain in ignorance of the existence of the hernia.¹ Upon inquiry it may be elicited, if the patient enjoys ordinary intelligence, that before the nausea commenced, a sudden sensation of uneasiness was felt in the abdomen, especially about the hypogastric region; that this was followed by a repeated desire to go to stool, with tenesmus, and that nothing but a little flatus escaped.

Nature of the vomit—The composition of the vomit varies at different stages of the illness. At first it usually consists of the substances last swallowed; next, principally of yellow bilious fluid, which after a time changes to a greenish hue; until at last the colour changes to brown, and resembles more or less closely, especially in odour, a mixture of faeces and water. It is then termed feculent or stercoraceous.

During the active stage of vomiting the sufferer is unable to retain anything in the stomach for any length of time. But as an extreme state of prostration of the nervous system becomes more and more imminent, and also if the narcotic effects of opium be induced, the irritable condition of the stomach subsides, and may cease altogether. The surgeon must not, however, be thrown off his guard by this apparent calm. His anxieties must not cease in consequence of this composed state of the patient. On the contrary, it betokens a most dangerous depression of the vital powers, a degree of exhaustion from which some persons never rally.

The stage of prostration is now established. The pulse, which during the earlier hours of the attack was more full, and beat more frequently than normal, and which, as the vomiting continued, became weaker and more rapid, now beats slowly and with little force. The surface of the body is chilled; the hands and feet are blue, their integuments shrivelled, the aspect of the countenance is one of anxiety and distress; a peculiar expression as of suddenly increased age is very characteristic; the muscular system has lost its tone; the tongue is dry, furred, and frequently

¹ *Importance of searching for a hernia in certain cases.* In consequence, therefore, of the fatal results which almost inevitably ensue if a strangulated intestine be not speedily liberated, it is the paramount duty of every medical man, when called upon to afford relief in cases of continued vomiting, to examine those regions of the abdominal walls in which hernial protrusions take place.

After long hospital experience, during which time the number of cases of hernia coming under our observation has been very large, many of which had been entirely overlooked until the last stage, we feel it our duty to allude to another cause of destruction. Among the poor it has frequently happened that a friend of the sufferer had gone to a chemist's shop to relate the symptoms, and vomiting and constipation being the most prominent, drastic purgatives were prescribed, and repeatedly swallowed by the patient. Thus, not only was valuable time lost, but treatment of the most injurious kind adopted.

brown; and the secretion of urine falls below the normal standard of quantity. At this stage the hernia is sometimes reducible. The most gentle manipulation suffices. This occurs more commonly in inguinal hernia than femoral. It probably depends upon the relaxed condition of the abdominal muscles, and the removal of the constriction they once exerted around the mouth of the sac; in the same manner as chloroform exerts a beneficial influence. Death occasionally takes place at this period of the attack. This fatal issue is attributable to the extreme prostration of the nervous system induced by protracted vomiting; for in after-death examination of such cases we do not discover any organic lesion to cause it.¹

The next stage, characterised by distinct symptoms, is after the development of peritonitis. But this does not always occur over so large an extent of surface as to excite grave apprehensions for the result. Peritonitis is often purely local, and confined to a small area around the region in which the hernia is situated. Perhaps the local inflammation is only just sufficient to produce adhesions between the orifice of the sac and the protruded intestine. However, when general peritonitis is developed, the usual symptoms of the disease are well marked. Niccough is especially regarded as an unfavourable indication. Peritonitis, in the most severe form, arises when the walls of the bowel have been perforated by ulceration, thus allowing their contents to escape into the peritoneal cavity. Intense abdominal pain immediately follows this accident, collapse supervenes, and death speedily releases the sufferer.

The last stage is collapse: the sufferer, although not physically dead, yet seems to linger on the threshold of that state. The patient may continue some hours pulseless; the extremities cold, and the breath also: the facial aspect deathlike; the power of speech but slightly impaired; until a sudden change comes over the features, and life has departed.

We have before described the pain felt in the hernial tumour. Besides this there is a peculiar sensation of tightness or constriction referred to the umbilicus. This is a highly characteristic feature of a strangulated hernia. The patient describes the suffering as resembling the effect which would be produced by encircling the mesogastrium with a tightly-drawn cord. To this is sometimes added a dragging sensation, extending from the epigastrium to the hypogastric region.

Pain, regarded as a symptom of peritonitis, is an uncertain indication. This disease frequently exists without much pain being experienced, and even pressure on the abdomen is endurable without causing complaint. Pain is more particularly absent in those cases where peritonitis arises without ruptured bowel. If, however, fecal extravasation be the cause of the peritonitis, then the pain immediately becomes intense, often agonising, indeed pathognomonic of that occurrence.

Prognosis of strangulated hernia.—Undoubtedly it is to the length of time which the bowel is allowed to remain strangulated, and to the delay in the performance of the operation for its liberation, that the high rate of mortality must be generally attributed. This circumstance cannot be too strongly impressed upon the mind of the patient; nor can the medical attendant act too promptly in the employment of the only treatment which can avert such untoward results.

The late Mr. James, of Exeter, was evidently surprised at the mortality occurring in the hospitals of London when he observes: 'There can be little doubt that the majority of these fatal cases (of hernia) were the victims of time; . . . this, I am

¹ Mr. Obré showed a dissection of a case of entero-epiplocele illustrating this fact, at the Pathological Society (*Path. Trans.* vol. vii. p. 219). A woman, 53 years old, died after four days' strangulated bowel, without receiving medical advice. After death a small portion of intestine was found perfectly strangulated in the left femoral ring; it was intensely blue, but its tissues unaltered. The small intestines were preternaturally red, but not inflamed.

M. Malgaigne also reports a case of the same kind. Strangulation of the intestine had existed eight days, when the woman died. There was neither gangrene, ulceration, nor peritonitis. He then observes that we see that a strangulated hernia excites such an extreme depression of the vital powers that patients may succumb without any anatomical lesions appearing to produce that event (*L'Union méd.* 1854, p. 248).

aware, is an error little imputable to the distinguished surgeons by whom these operations were performed. It is generally the unfortunate patient who is the cause of his own disaster.¹

This statement very truthfully represents the state of the case, in some instances, without doubt—in those, for example, in which the patient, being conscious of the existence of the rupture, conceals that knowledge from his medical attendant, or refuses all interference beyond external or internal therapeutical agents. It does not remove the imputation of neglect from him, who, when the case is under his medical care, leaves his patient for several hours in suffering; nor can it justify the delay which is caused by a surgeon who, duly appreciating the nature of the illness, refrains from liberating the constricted bowel, or asking others to do so, after appropriate means have been unsuccessfully employed to return it by the taxis.

We have never known an instance of a patient dying in consequence of the bowel being liberated at too early a period; but we have had to operate upon many whose chances of life were absolutely sacrificed by the inexcusable delay which had occurred before the patient was submitted to the operation. We make this assertion after a large experience, extending over many years.

Why is it that the mortality attending strangulated hernia is so large? How does it happen that every writer upon this disease and every hospital surgeon has to deplore the condition of patients subjected to the operation for the liberation of the bowel? The average annual mortality in this metropolis caused by hernia, and published by the Registrar-General in 1861, amounted to 148.² This average was

FIG. 162. — The Injured Tissues of a Knuckle of Small Intestine which had been violently confused during efforts made to reduce it.

The dark shade between the serous and mucous membranes represents blood extravasated in the walls. The whole of the knuckle was gangrenous, although it had been strangulated only a few hours. The lines of ulceration in the mucous membrane are distinctly seen. (Copied from a coloured drawing and preparation in Guy's Hospital Museum.)

calculated from the total number of deaths from this cause registered during the previous thirteen years. The highest number recorded is for the year 1862, viz. 170; the lowest in 1850, 128. We may assume that the increase of population, and greater accuracy on the part of those certifying the causes of death, may account for the difference between these extremes—42. Now, judging from the condition of the cases which have come into hospital under our own care, we believe we are correct in stating that the mortality might be reduced at least by two-thirds if the liberation of the bowel was effected immediately after the failure of judicious attempts to reduce the hernia by the taxis, assisted by proper means, or soon after the vomiting of fluids regurgitant from the intestinal tube. We do not hesitate to pronounce this judgment after carefully ascertaining the facts of the cases which have fallen under our own treatment. For example, in inguinal hernia: of eight fatal cases, three were incurable in consequence of the condition of the bowel, irreparably diseased by long-continued constriction; two others were in a similar state from the bowel having been injured by violent compression employed to reduce it. Cases of femoral hernia are even still more fatal from the causes above mentioned. In twenty out of twenty-

¹ *Practical Obs. on the Operations for Strangulated Hernia*, p. 79, 8vo. 1859.

² *Summary of Weekly Returns of Births and Causes of Death in London*; published by the authority of the Registrar-General, 1863.

eight, the immediate cause of death was attributable to the disease of the bowel which had formed the hernia; this morbid state depending upon injury, over which the mere liberation of the bowel exerted but slight influence towards repair. For it should be remembered that the simple replacement of the viscus in the abdominal cavity does not ensure the restoration of its functions, the surgeon only replaces it in that situation where the reparative powers of nature are most likely to exert their influence with activity; and that if the tissues of the hernia, when reduced, are incapable of performing their functions, those of the intestine cannot be performed, and therefore death must ensue. In several of these cases the disease of the bowel was rendered still more surely irreparable by the pressure to which it had been subjected in the taxis; and in two instances the damage inflicted by this means was so great as to have absolutely killed the entire coil of intestine which was in the sac (fig. 162).

But all the causes which produce the morbid conditions of the bowel above mentioned, and more fully detailed in preceding pages, can be prevented. They may not be always under the control of the medical attendant, nor amenable to surgical skill; but we confidently promulgate the doctrine that the salvation of life in cases of strangulated hernia entirely depends upon the liberation of the bowel at the earliest moment practicable; and the converse may be predicated, that the destruction of life will inevitably ensue in proportion to the length of time the constriction has existed, with its constitutional consequences, and the prolonged and forcible taxis employed.

The vital importance of liberating the bowel from constriction at the earliest moment cannot be over estimated. As upon the speedy accomplishment of this the salvation of life depends, a little precipitate action may even be forgiven, so hazardous is the position of a patient with the bowel strangulated. But, what is the risk attending the operation of exposing the hernial sac, dividing the impediment to the reduction of the hernia, and reducing it, even should the peritoneal sac require to be opened? Practically, none. In comparison with that of leaving the bowel strangulated, it is harmless.

To what cause, then, may we attribute the culpable negligence of those who leave the poorer classes of the community in this most perilous moment - in a condition replete with jeopardy, fraught with results hazardous in the extreme? It would seem that the embarrassment and the delay are caused, not by surgeons being timid and slow to propose a remedy, but from their really being ignorant of the amount of mischief certain to arise by allowing the constriction of the bowel to continue.

We once heard a physician relate the following circumstance: Being asked to see a poor woman who had been vomiting for several hours, he discovered a hernial swelling. He suggested that a surgeon should immediately see the case, intimating that an operation was urgently needed. The gentleman in attendance replied, 'But will it not be desirable to wait until the vomiting has ceased before the performance of the operation?'

Can any principle be deduced from the facts detailed, to serve as a guide in determining the moment at which the attempts to reduce the hernia by the taxis should be given up, not only as hopeless of good results, but fruitful of pernicious effects, and a cutting operation be urged as the only safe means to liberate the bowel from constriction? We may certainly now assert this without fearing the accusation of too great precipitation: when the period has arrived at which it is certain, from the nature of the fluids vomited, that regurgitation of the contents of the duodenum and jejunum has taken place, any delay in effecting the reduction of the bowel is certain to be attended with progressively increasing evils. If there be evidence of regurgitation from the ileum, the condition of the patient is still more hazardous. Even assuming that the case be now seen for the first time at this period, and that attempts have not been made to reduce the protrusion, delay is inadmissible. The administration of chloroform should be recommended at once, with an understanding between the patient and the surgeon that the operation should be immediately per-

formed if, when its anæsthetic effects are fully developed, he fails to reduce the hernia by manipulation.

M. Desault, fully appreciating the injury too often inflicted on the hernia by the injudicious and violent employment of the taxis, wrote: 'Always think favourably of a case of strangulated hernia when the taxis has not been used.'

Several years since I operated upon a case of femoral hernia in a woman who had been labouring under symptoms of strangulated intestine for fourteen days. This was carefully ascertained. The bowel was thickened, and like a piece of leather. TAXIS had never been employed, and this patient recovered perfectly.

Treatment of irreducible hernia. Reduction of the hernia by the taxis.—The endeavour to reduce the hernia, which consists in displacing it from its abnormal position, and passing it through the orifice of the sac into the peritoneal cavity, by dexterous manipulation, is termed the use of the taxis. Of course, the first desire upon the part of the surgeon is to accomplish this feat. But all attempts to replace the bowel in the abdominal cavity should be relinquished until the circumstances attending the special case under observation have been carefully ascertained and considered.

The principal circumstances to which attention should be directed are as follows:—

1. The kind and variety of the hernia regarded in its anatomical relations.
2. The duration of its existence: whether it be of old standing and slow formation, or of recent and sudden development.
3. The constitutional condition of the patient at the immediate moment, as influenced by the present illness. The hour at which vomiting commenced; and the variations which have taken place in the composition of the fluids vomited should be determined with exactitude.
4. The state of the tumour. Its usual size when not causing illness; its bulk before vomiting commenced; the changes which have taken place in it during this stage; the pain to which it gives rise, it merely local or extending into the abdomen, with or without manipulation; the condition of its coverings; its probable contents, so far as may be conjectured by the evidence, assisted by touch and sight.
5. The treatment already adopted by the patient, the friends, or other persons, before the observation of the surgeon.

These are all subjects upon which profound reflection and serious meditation are urgently demanded.

Injurious effects produced by the taxis.—It is necessary to state once more that irreparable injury is frequently inflicted upon the herniated bowel by violence used at all stages of the illness. The danger of any mischief occurring by the use of the taxis increases in proportion to the length of time the bowel has been strangulated. This necessarily arises from the tissues of the viscus becoming less and less able to resist the pressure of the hand in consequence of a morbid state due to the constriction.

The principles by which the surgeon should be influenced, when he is desirous to reduce a hernia without the use of the knife, or by the taxis, are these:

1. Before vomiting commences. It is evidence of sound judgment to abstain from manipulation of the tumour in this stage, and until other remedial means have been tried, except with the object of forming a correct diagnostication of its nature. The taxis, unassisted, often fails to replace the protruded viscus, and in many cases upon which we have been required to operate, patients have stated that the vomiting did not commence until after the use of prolonged and forcible pressure of the tumour. If the case be one of old and slowly-forming hernia, commonly reducible, which has become more painful and larger than usual, for a few hours only, the patient should be enjoined to lie on the back, the pelvis being elevated, and the knees flexed. Or, in other words, the abdominal muscles must be relaxed, by posture, as much as possible. Warm fomentations are to be disposed over the

region of the mouth and neck of the sac, especially in children; and the tumour, if it be a scrotal hernia, supported, or never allowed to be pendent, thus dragging on the neck and mouth of the hernial sac by its own weight. The lower bowel may be induced to empty itself by administering an enema of warm water with a long flexible tube, and tincture of opium should be given in doses suitable to the age of the patient. It is desirable, however, that a full dose be given to adults: and with this view thirty drops diluted with camphor mixture is not too large a quantity. A few hours may be allowed to pass away in order to afford time for this treatment to take effect, unless urgent symptoms arise.

Some patients cannot maintain the posture just described, or it might be highly injudicious to enforce it. The principle of relaxing the abdominal muscles may then be carried out by allowing the patient to lie on the side of the trunk; but even then the hernial tumour must be carefully supported.

Under the influence of this treatment the patient very often falls asleep, and on awaking finds that the protrusion has returned into the abdominal cavity. Now, should that happy result not have occurred, it will be desirable to manipulate the tumour gently, which perhaps has become soft and flaccid. This must be done upon some fixed principle. A successful issue will not accrue unless the pressure employed be directed with intelligence. The anatomical relations of the protrusion with the mouth of the sac and the apertures in the abdominal walls must be carefully considered; and the course or direction which the hernia takes in its descent should be strictly regarded in all efforts undertaken with a view to its reduction. The patient must be disposed in a posture to relax all the abdominal muscles which can in the slightest degree contract around the mouth of the sac. This part of the sac and its neck should be fixed, as far as practicable, with the fingers of one hand, whilst the fundus of the tumour is held in the palm of the other. This proceeding can only be adopted when the tumour is large. The object desired by the manipulator is twofold: first, to dilate the mouth of the sac; and, secondly, to diminish the bulk of the protrusion. The area of the orifice of the sac may be enlarged by employing the widest part of the body of the tumour as a fulcrum, over which the tissues composing that part of the sac may be stretched. If an enterocele be under treatment, the size of the protrusion may be diminished by partially emptying the tube of its contents, perhaps by relieving the congested blood-vessels: and, in some cases, the tension of the sac is lessened by pressing the serous effusion it may contain into the peritoneal cavity. That fluid being thus disposed of, the operator is enabled to exert a more direct influence upon the hernia.

2. During the stage of vomiting. It behoves the surgeon to be always on his guard in the use of the taxis, when vomiting is coincident with a hernial protrusion. The longer the time, indeed, the vomiting has lasted, the greater the risk in manipulation of the tumour. If before the commencement of vomiting delicacy of handling be important, how much greater now is the necessity for gentleness when the state of the protrusion, as indicated by the symptoms, can be foretold! Before vomiting occurred, the tissues of the bowel were comparatively healthy, and the damage inflicted by pressure induced a morbid state. After vomiting, especially if it has been persistent some hours, and it has become feculent, the tissues have been rendered morbid by the constriction to which they have been subjected. Ill prepared, then, are they now to resist pressure, and the effect of violence will surely be to bruise or lacerate them.

The measures which were employed in times past to enable the surgeon to apply the taxis with more effect, and which were generally prescribed at this stage of a case of hernia, need no more than simple mention here. An exception may be taken in favour of opium. There is one period at which its administration is attended with decided advantage. After carefully watching cases of strangulated hernia, we believe we have correctly noticed that there is a short interval of repose which continues until regurgitation takes place from the small intestines. This occurs when the stomach is empty, as the result of vomiting two or three times. If this moment be seized, and a full dose of opium in solution, with a little stimulus, be administered,

the hernia may sometimes be reduced by the taxis. But when once the vomiting of regurgitated fluids is an undeniable fact, the inward administration of medicines is pernicious.

We believe the statement to be correct, that all other modes of treatment have been abandoned in favour of the administration of chloroform. Why? it may be asked. An analysis of the effects of those therapeutic agents formerly in vogue shows that they exerted an influence over the constitutional and local causes preventing the reduction of the hernia, similar to that which is now accomplished by chloroform more speedily, more certainly, with less risk to life, and under circumstances much more within control. The constitutional remedies were bleeding, the warm or hot bath, and tobacco-enemata; all of which exert a powerful but uncertain influence over the vascular, nervous, and muscular systems; on which account they cannot be employed without some risk, arising from effects which are often uncontrollable and persistent for a longer period than is desirable. But the anæsthetic qualities of chloroform, together with the complete suspension of all voluntary muscular action induced by the inhalation of its vapour, renders this therapeutic agent of inestimable value, especially in those cases in which the abdominal apertures are under the influence of muscles controlled by the will, as well as stimulated to involuntary contraction by local irritation.

It is especially beneficial in all kinds of inguinal hernia. Its good effects are most striking in cases of hernia into the vaginal process of the peritoneum occurring in infants and youths, as also in those varieties developed slowly in adult life, and which have existed many years. In fact, the operation for the liberation of a strangulated inguinal hernia in middle age and elderly adults is now rarely required in comparison with the frequency of its performance in past years. As soon as voluntary muscular contraction ceases, then the tumour gradually becomes softer or less elastic, under gentle and well-preconcerted pressure, smaller and of different shape, until at last the hernia escapes from the embrace of the mouth of the sac with a sudden jerk.

The sensation the surgeon experiences when it quits the sac and enters the peritoneal cavity is very peculiar and striking. So characteristic is this of the complete freedom of the bowel from constriction, that in its absence the expert surgeon immediately suspects that all is not quite right.

Usually, vomiting ceases after the reduction of the hernia at once. Occasionally, however, it may continue from the effect of the chloroform alone; but the pain in the abdomen is immediately less, and quickly ceases altogether, especially that characteristic, dragging pain across the mesogastrium.

The patient should maintain the recumbent posture for a short time, with the abdominal muscles relaxed. We do not consider it necessary to place a pad and bandage over the mouth of the sac. Diet of a bland nature and semi-fluid consistence may be allowed in small quantities, and all stimulation of the alimentary canal by aperient medicine must be avoided. As soon as the injured viscus has recovered its functions, the bowels will act spontaneously. Stimulants should be administered according to the constitutional depression existing at the moment.

But great caution as well as discretion are necessary qualifications on the part of the surgeon when he manipulates the tumour. During the insensibility of the patient there is considerable risk of bursting the intestine or lacerating the hernial sac. For twelve hours, or even perhaps for twenty-four in old protrusions, after the first vomit, the danger of using the taxis with sufficient violence to burst the bowel is not very great; but so much damage may be inflicted on its tissues as to preclude all hope of the repair of the mischief. When twenty-four hours have expired, during which time the bowel has been strangulated, it may be very easily burst by forcible pressure, especially if during the latter part of that time the patient has been vomiting fluids which have regurgitated into the stomach from the small intestines. If there be hiccough, the taxis is inadmissible.

The indications of burst bowel are very characteristic. If an enterocele, the hernia glides away from the pressure of the finger, and consequently the tumour

disappears. This act is not, however, accompanied with that sudden and peculiar sensation which the replacement of an unburst bowel within the peritoneal cavity produces. The patient immediately complains of severe pain in the abdominal region; vomiting ceases, but retching and hicough may arise instead; collapse rapidly supervenes, and death closes the scene in a few hours. In some instances inflammation and suppuration have taken place in the sac, and extending to its coverings, an intestinal abscess has been developed. A fistulous opening thus becomes established, which communicates with the interior of the alimentary tube. (See preceding remarks on 'Artificial Anus,' p. 767.)

There is a period, then, 'when the symptoms of the rupture have gone very far, that it is imprudent to reduce it, even if possible; but as it is impossible, perhaps, to tell when the mortification of the gut is gone too far for reduction, it will, in general, be attempted while life exists, with the hopes of a cure. Upon the other hand it may be asserted, or supposed, that if it is not reduced, the person must also die; but this is not so certain as the other; for the mortification of a gut simply does not kill—it only kills from its consequences; and there is a material difference between a mortified gut out of the belly, and one within. The consequence of one within is absolute death; but the one without in general endeavours at a cure, by producing inflammation and suppuration of the parts, which is producing a fistulous orifice, or artificial anus.'¹

Cold applications.—Considerable advantage attends the application of cold over the tumour. But when either ice or freezing mixtures are used, their action must be widely extended over the mouth, neck, and body of the sac. The local effects of cold are to diminish the bulk of the protrusion, by exciting contraction of its blood vessels; to retard inflammatory processes; and, by reducing nervous sensibility, to permit an advantageous manipulation of the tumour. Frigorific applications are valuable agents when there may be unavoidable delay in obtaining chloroform, or in liberating the bowel from constriction. The moment for their employment is after vomiting has commenced, and we consider they are more suitable to cases occurring in the adult than in the earlier periods of life. The advantages attending their employment, however, are so trifling in comparison with the injury certain to be inflicted on the bowel by prolonged constriction, that it is safer to proceed at once to its liberation by operation, than to allow any great length of time to elapse in the expectation of an advantage, which is in any case doubtful. In practice, cold applications can only be regarded in the light of very useful prophylactics. After marked indications of strangulated bowel have existed twenty-four hours, cold as a local therapeutic agent is scarcely admissible, as a rule, on account of the delay which must necessarily occur at this important moment.

The distressing thirst, an accompaniment of continued vomiting, is greatly allayed by taking small pieces of ice into the mouth.

The administration of every kind of purgative medicine must be scrupulously avoided in all stages of strangulated bowel. When swallowed, they are usually speedily vomited; and therefore it is sometimes suggested that under these circumstances they cannot produce a bad effect. This, however, is not always the case. We have seen fatal results ensue from diarrhoea quickly supervening after the bowel had been reduced, the exciting cause of which was referable to purgative medicines taken during the stage of vomiting.

A purgative enema seems to exert a beneficial effect occasionally. But after one has been used in the early period of the attack, a repetition of this treatment is perhaps hurtful in the majority of cases.

Many other local and constitutional remedies have been employed with the intention of assisting the reduction of a hernia, and with occasional benefit. But the uncertain result which attends their employment; the disease, which is always progressive in the herniated viscus; and the risk to life, a certain accompaniment of continued strangulation of the hernia, and its attendant consequences—deter the

¹ *Hunterian MS. Cat. of the Mus. Roy. Coll. Surg. Eng.* vol. iii. p. 117.

experienced surgeon from persisting in entertaining the hope of reducing the protrusion by the taxis, after chloroform has been fully administered, and the hernia remains unreduced.

Herniæ have been replaced whilst completely reversing the ordinary position of the trunk, by keeping the head nearest the ground and the pelvis upwards. A patient may be placed in this posture (head downwards) by hanging over the back of a man, or over the side of a high bedstead or sofa, whilst the knees are at the same time flexed. Another method consists in encircling the mesogastrium with a folded sheet or round-towel, and at the same time drawing the contents of the pelvic region from below upwards, whilst the patient lies in a recumbent posture.

When the hernia is but recently strangulated, and it is an object to reduce it as speedily as possible, without a cutting operation, any method suggested which has been once successfully employed is perhaps worthy of a trial.

Injuries inflicted and accidents occurring in the use of the taxis.—These affect the following structures, separately or in combination; but we may consider independently—

Those affecting the hernia; those affecting the sac; and those involving the tissues covering the sac.

The hernia, whether consisting of a hollow or a solid viscus, may be bruised, and its blood-vessels ruptured. Under these conditions blood is extravasated into the tissues composing it, producing either patches of ecchymosis, or, when an enterocele exists, layers of effused blood appear between the different coats of the viscus.

The tissues of the bowel being delicate, they are more commonly subjected to irreparable injury by violent taxis than the omentum. The presence of this structure, perhaps, often tends to prevent the serious mischief just described. The degree of irreparable injury inflicted on the bowel cannot be accurately estimated by the length of time the symptoms of strangulation have existed. Much rather does it depend upon the violence and prolongation of the attempts employed in the taxis. At any moment during the first twenty-four hours succeeding the first act of vomiting, the entire portion or coil of bowel in the sac may be so disorganised by pressure, that its vitality is entirely destroyed, and so literally killed, that nature throws off the part by the processes usually attending the separation of living from dead tissues. Under these circumstances, the entire calibre of the canal is divided, and an artificial anus is formed: or death takes place in consequence of extravasation of the stercoraceous material into the peritoneal cavity. Sometimes the tissues of the bowel are cut by pressure against the orifice of the sac, or the structures surrounding it; as in femoral hernia, against the free edge of Gimbornat's ligament. (See fig. 162.)

After the expiration of twenty-four hours, the constriction to which the bowel has been exposed having led to inflammatory effusion into and softening of its textures, there is great risk of bursting the tube. This rent usually occurs at the convex border of the gut, at the furthest point from the mesentery, and corresponds with the direction of the circular contractile fibres.

Another effect of violent compression is to cause the mixture of blood and coagula with the serum in the sac, and flakes of lymph or puriform effusion arise from the same injurious interference. The local and constitutional indications of these injuries have been described in a preceding page.

Injuries of hernial tumours by accidental violence.—We may here briefly describe the treatment of those injuries which happen to hernial tumours from accidental circumstances, during the pursuit of the ordinary avocations of individuals afflicted with reducible as well as irreducible ruptures. The reader will derive more information on this subject than it is possible to introduce here, by the perusal of a most interesting paper entitled 'On the Proceeding to be adopted in a Case of Injured Intestine from a Blow on a Hernial Sac,' by the late Mr. Aston Key.¹

A simple contusion is the mildest form of injury. Should the signs of more

¹ *Guy's Hospital Reports*, 1842, vol. vii. p. 261.

severe mischief be absent, the hernia may then be returned. It is important, however, that the patient abstain from bodily exertion, and the alimentary canal be kept in a state of repose. If the violence of the blow have been sufficient to cause inflammation and ulceration of the gut, the slightest indication of any such secondary mischief must be watched with the most anxious care, and the favourable moment seized when an incision into the tumour will allow the escape of the contents of the alimentary canal, and by this proceeding avoid the risk of extravasation into the peritoneal cavity.

But when there are plain indications that the primary effect of the violence has been to lacerate the intestine, which by chance was contained in the sac at the moment the injury was inflicted, time should not be wasted in adopting palliative measures; but the hernial sac must be freely cut open, and thus a ready means of escape be made for the stercoraceous fluids. The symptoms indicating a wound of the intestines are described in the essay on INJURIES OF THE ABDOMEN.

Another variety of injury of a hernial tumour is when the patient has an irreducible epiplocele. The omentum is adherent to the mouth of the sac, and entirely blocks it up, as it were, whilst the body of the sac remains as a simple closed serous cavity. A contusion of such a tumour excites inflammation and suppuration within the sac. Considerable embarrassment may be experienced in precisely diagnosing the exact nature of the disease.

Injuries of the hernial sac.—There are two varieties of injury which produce important effects on the sac containing the hernia. Both of them render a case of strangulated hernia exceedingly complicated and embarrassing. The violence causing the mischief may be applied to the tumour either by the sufferer or another person; but considerable force is requisite to rend or tear the tissues composing the sac, or to separate it from its surrounding connections. These injuries more frequently happen in association with long-continued pressure than after short trials of the taxis. The two varieties are as follows:

A. *By displacement.*—The sac is detached, to a greater or less extent, from the surrounding structures. Those parts of the sac called the orifice and neck are more frequently affected by this injury than any other portion. They become detached from the inner surface of the internal abdominal fascia. Together with these, that portion of the parietal peritonæum immediately circumjacent to the sac's mouth is also severed from its attachments, and in this manner a pouch is formed within the fascial membrane of the abdomen, into which the hernia may be forced; and being retained therein, is lost to touch and sight. Sir Charles Bell has recorded a case which illustrates this injury.¹

It is stated that the entire hernial tumour may be pushed within the abdominal walls, in a mass, whilst the hernia is still strangulated by the orifice of its sac. This injury was first described by French writers, under the appellation of 'réduction en bloc.' However, of late, examinations made after death indicate other lesions to be the probable causes of the disappearance of the hernia, in some cases; and certainly afford conclusive evidence that such an accidental disposition of the sac, when strictly examined in an anatomical point of view, must still be regarded as a very rare occurrence indeed. We refer the reader to Mr. Luke's paper for further information.²

In offering the following explanation of many of these cases, we court the inquiry of future observers, to support its correctness or to prove it to be erroneous.

The tissues of the scrotum are very loose, and readily change their position. Every observer must have noticed the variable length of the spermatic cord, between the external abdominal ring and the testis at different times. The hernial sac, attached to the anterior surface of the spermatic cord, also varies in length in like manner. When the hernia occupies the sac, the latter extends lower than when it is empty, in which last state it perhaps only just emerges from the inferior outlet of the inguinal canal. Now let its mouth and neck be detached from the internal ab-

¹ *Lond. Med. Gaz.* 1828, vol. i. p. 485.

² *Med.-Chir. Trans.* 1843, vol. xxvi. p. 150.

dominal ring, and the hernia still strangulated by the margins of the orifice be pushed inside the abdominal walls. The fundus of the sac attached to the tissues of the scrotum is not on this account severed from those connections, but merely ascends towards the inguinal canal, and lies partially within it with its walls in close contact, which, being rather thin, are not very recognisable. The fact that this part of the hernial sac has been often found in this situation during the progress of an operation for the liberation of the strangulated gut, is attested by the reporters of those operations.¹

B. By laceration or bursting.—As the effect of forcible and long-sustained compression of the hernial tumour, the delicate serous membrane of the sac is rent, burst, or torn, and the hernia makes its escape through the aperture into the sub-serous connective tissue. Its course outside the peritoneal sac is advanced by continued pressure; and detaching the connections of the neighbouring peritonæum, it forms for itself a pouch between that serous membrane and the internal abdominal fascia.

The part of the sac a little below its abdominal orifice or mouth, usually styled the neck, which lies in the inguinal canal, is most frequently burst along its posterior surface. This injury is more commonly produced in that variety of inguinal hernia, the sac of which is constituted of the vaginal process of the peritonæum, whether the hernia be in contact with the testis or not. It is inflicted with remarkable facility when the patient is fully under the anæsthetic influence of chloroform, especially if he be also youthful. This accident is easily imitated, after death, upon a subject in which the neck of the hernial sac happens to be rather long, by cutting an opening in its posterior wall, and pushing the finger in a backward direction. The course which the finger takes is that one which the hernia would pursue.

The indications of the accident having taken place are as follows: the tumour becomes flaccid, and therefore smaller, which alteration in its features is probably owing to the serum which the sac contained being squeezed through the rent into the connective tissue around the sac; the bulk of the tumour slowly diminishes as the pressure is continued, until at last very little, if anything, can be felt, but the surgeon has failed to experience that sudden jerk so characteristic of the escape of the hernia from the gripe of the mouth of the sac, as it enters the abdominal cavity; and if he have had much experience of the reduction of hernial protrusions, doubts will arise in his mind as to the probable direction this one has taken. After the effects of the chloroform have passed away, all the symptoms of strangulated bowel recur, and perhaps with increased force. Even the tumour itself may reappear, and recede on the application of slight pressure.

Now all these circumstances are highly characteristic of the accident that has occurred; and there remains but one proceeding to be adopted immediately. It is this. The hernial sac must be exposed and opened. Perhaps it may appear to be empty; and even the finger passed upwards and along the inguinal division of the sac enters a cavity through a well-defined aperture, in which intestine is felt. This abnormal aperture may be mistaken for the internal ring and the cavity into which it leads, that of the abdomen. Acting upon this belief, however, would lead to the commission of a fatal error; one which, if not detected at the moment, will surely compromise the life of the patient. An effort must now be made to draw the bowel out, if it does not come forth spontaneously; and when this is accomplished, the true mouth of the sac will be discovered by passing the finger upwards along the anterior surface of the mesentery. By the orifice of the hernial sac the protrusion is firmly constricted. The constricting tissues, therefore, require to be cut; after which operation, the exercise of great care and caution is needed to prevent the entrance of the hernia once more into the abnormal space outside the peritoneal cavity. As the salvation of life depends upon the return of the protrusion through the natural orifice of the sac, considerable freedom in the use of the knife is justifiable, if the attainment of the desired end is thus facilitated, and the risk of failure in doing this thereby removed. All cases of this description not only give rise to great embarrass-

¹ *Med.-Chir. Trans.* 1850, vol. xlii.; see tables at end of paper, p. 278.

ment and difficulty, but they are also associated with very unfavourable consequences and results.

Injuries to the coverings of the hernial sac.—A very short description will suffice to indicate the nature and effects of the injuries inflicted on the tissues covering the sac by the use of unjustifiable violence in attempting to reduce a hernia by the taxis. We have seen the results of contusion; namely, ecchymosis of the integuments; extravasation of blood and cedematous infiltration into the subcutaneous tissues covering the sac; and inflammation of all the structures together, passing on to suppuration, sloughing, and phlegmon, extending to the neighbouring regions. Those local morbid conditions require the ordinary topical measures suited to them.

The disappearance of the hernia in consequence of its passage from one sac into another;—intra-parietal.—We may here allude to those rare cases of inguinal hernia which are complicated with an intra-parietal sac. Anatomically examined, the hernial sac in these cases consists of two parts; that division which passes along the inguinal canal into the scrotum, and that one which is lodged in the walls of the abdomen. A full description of these curiously developed sacs is given in the section of this paper devoted to inguinal hernia. Now when the hernia is strangulated by the ventral orifice of the sac, and it occupies the scrotal division, it may be pushed by the taxis, even when employed with the utmost care and skill, into the other sac, and thus, the tumour disappearing, the surgeon considers the hernia reduced. The constitutional symptoms, however, quickly indicate that this is not the case. By inducing violent action of the abdominal muscles, or making the patient stand erect, the hernia will sometimes reappear. Under any circumstances, the liberation of the bowel is demanded, and in the necessary operation to accomplish this end great care is required to avoid passing the bowel from one sac into the other, instead of into the abdominal cavity.

The operation for the removal of the impediment to the reduction of the bowel, or the liberation of the hernia.—The culminating point in the treatment of every case of strangulated enterocele is reached when the impediment to the reduction of the bowel must be removed by a cutting operation. This of course occurs after the failure to reduce the protrusion by the taxis.

The part of the practical surgeon is not only to know truth, but to apply it; and however repugnant to the feelings of the patient or creative of alarm the thoughts of an operation may be, it is his paramount duty to urge concurrence in this step, as it alone offers the surest prospect of the salvation of life.

By too many medical men the cutting operation seems to be regarded in the light of a last resource, and one which it is improper to use until danger to the life of the patient appears imminent. But the sooner that this fatal error is eradicated, the sooner shall we discover upon what fallacious views it has been based. We believe that death resulting from strangulated bowel would be a rare occurrence, if it were practicable to return every strangulated enterocele within twelve hours after the commencement of the symptoms, even assuming that the cutting operation be required to accomplish that end in every case. For let this conviction be firmly impressed upon the mind, that death results not from the operation, but because the operation was not performed at the right moment.

Every medical attendant upon a case of strangulated hernia should reflect on these indisputable facts, that so long as the viscus remains in that condition the life of the patient is slowly ebbing; that to his judgment and foresight has been committed the safety of the sufferer; and that upon his discretion, firmness, and resolution hangs the fatal issue. For it is no exaggeration to say, that each minute as it elapses carries with it the chances of recovery further and further away.

We hope that the mortality arising from strangulated hernia is not now so large as it once was.¹ Nevertheless, at this moment it is excessive; and when we know,

¹ Mr. Hey states, that when he entered upon the profession of surgery, now one hundred years since, 'the operation for the strangulated hernia had not been performed by any of the

and all professing surgery should know, how surely the liberation of the bowel tends to save the life of the patient, why is it not done the moment all other measures have failed to replace the gut in the abdominal cavity? Some medical men do not seem to be sensible of, or to appreciate the vast amount of injury which is certain to accrue from the persistent vomiting, nor to value the indications derivable from the character of the vomit. They most assiduously attempt to check the vomiting by administering medicines; but they utterly reject, at the suitable moment, the only means by which it is to be arrested.¹

The operation, kelotomy, herniotomy. The first part of the operation consists in cutting through all the tissues covering the hernial sac, carefully recognising their characteristics as they differ in the special regional varieties of hernia. Having reached the sac containing the strangulated viscus, the operator now determines upon the propriety of opening it and exposing its contents to sight and touch.

If he determines to cut the sac open, it should be done in this manner. The body of the sac is nipped up between the finger and thumb, and with exceedingly great care, to avoid at the same time including the walls of the bowel. An opening sufficiently large to admit a grooved director is next made with a scalpel, the sharp edge of which must not be directed towards the contents of the sac, but laterally. The side of the blade should be placed nearly flat on the tumour. By this management of the instrument, all risk of injuring the intestine is removed. A grooved director having been passed through the opening and firmly held against the inside of the sac, rather indeed stretching its tissues over it, they are freely divided, upwards and downwards, or towards its orifice and fundus.

Usually the escape of more or less serum is a sufficient indication that the hernial sac has been opened. But the operator should not be thrown off his guard by an absence of serum, when the sac has been cut, any more than by seeing a flow of fluid when it has not been even reached. The latter somewhat rare occurrence is due to the development of a cyst upon the hernial tumour, and is at once explained by passing the finger into a circumscribed cavity. For the variable conditions of the serum, see p. 769.

When an enterocele is under treatment, the intestine is brought into view as soon as the sac is opened; but in an entero-epiplocele it often happens that the omentum only is exposed. The surgeon then carefully raises this structure, for the bowel lies underneath in the majority of cases. It is wholly enveloped by it in some instances, when that arrangement termed an omental sac exists. In this case the omentum

surgeons in Leeds; and he adds, that he 'lost three patients in five upon whom the operation was performed' (*Practical Obs. in Surgery*, 3rd edit. 1844, p. 129). Are the results of the treatment of strangulated hernia more successful at the present day? We fear not.

¹ We may have expressed our views a little strongly, and thus laid ourselves open to criticism and animadversion; for we confess to have been a little influenced whilst writing these lines by an occurrence which took place at the time of doing so. A fine woman for her age, which was 71 years, known to be the subject of strangulated femoral hernia, was allowed to vomit persistently for between ten and eleven days. At this time she was sent to the hospital 'for the operation,' which necessitated a journey of several miles. She arrived cold and pulseless, though intelligent; the abdomen was tympanitic; she was in fact moribund. As soon as practicable the liberation of the bowel was effected. The escape of purulent fluid from the abdomen was sufficiently characteristic of the condition of the peritoneal cavity. In spite of warmth applied to the surface of the body and stimulants administered internally, she expired in a few hours after admission. Yet, during the ten days preceding, medicines had been prescribed to arrest the vomiting, taxis had been frequently employed, and the marvel was, as a friend who accompanied her expressed it, that she reached the hospital alive. What other result than death could have been anticipated? Ten days vomiting, and starvation for the same period, was surely enough to destroy life at the age of 71 years; but, in addition, she had a perforating ulcer at the point of junction of the upper division of the alimentary canal with the hernia, extravasation of stercoraceous matter, and diffused peritonitis. Nor is this case an isolated example of culpable negligence. Instances already recorded in books, and abundantly exemplified by reports in the weekly medical journals, abound in the metropolitan and provincial hospitals. Such misfortunes—for we deem it to be a misfortune that hospital surgeons have to treat cases of this kind—would never occur if the medical attendant could but be made to feel that his patient lies within the jaws of death until the intestine is returned into the peritoneal cavity.

requires to be carefully unravelled. We employ the last word in order to insure the use of much care and caution in the division of its tissues.¹

The condition of the bowel should be now carefully ascertained, for by the morbid state of its tissues the surgeon determines upon the propriety of placing it within the peritoneal cavity, or allowing it to remain outside of the abdomen. Simple adhesions of the bowel to the body of the sac may be gently broken down; but the greatest caution is required in this treatment of the hernia where it lies within the orifice of the sac, as by rough manipulation its tissues may be torn, when extravasation of the contents of the tube into the peritoneal cavity will take place. If the bowel is ruptured, it must be confined to the edges of the wound by sutures.

To reach the impediment to the reduction of the hernia, the point of the index-finger is now directed upon the anterior surface of the mesentery, towards the mouth of the sac. Should the end of the finger pass freely through the ventral orifice of the sac into the peritoneal cavity, when introduced with great gentleness, an attempt may be made to reduce the hernia without cutting this part of the sac. In the manipulation of the bowel great delicacy is required. The surgeon gently presses the distended coil, and if its fluid or gaseous contents escape into the continuity of the canal, it soon becomes flaccid. This condition may be regarded as an indication that the protrusion is reducible without cutting the orifice of the sac. On the contrary, if after delicate and continued digital pressure the knuckle of intestine continues to be tense, elastic, and round, the surgeon decides to enlarge the mouth of the sac by cutting it. Operators with little experience would do well to make use of a grooved director. This instrument is carefully passed upon the anterior surface of the hernia, its direction being guided by the index-finger of the left hand. It should be introduced into the abdomen sufficiently deep to be entirely clear of the constriction formed by the tissues around the protrusion, but not further. Careful examination is necessary at this step, to ascertain that the bowel does not overlap the borders of the director, nor lie between it and the anterior region of the neck and orifice of the sac. To avoid all risk of injury to the bowel, when that viscus is quite clear of the groove in the director, the instrument should be firmly pressed against the tissues which are about to be cut. A bistoury, specially constructed for this operation, is gently glided along the groove on the director, and a slight resistance is usually encountered as it passes through the constriction, which, however, yields as the cutting edge reaches, and in its passage divides, those tissues which cause the impediment to the reduction of the hernia.

When those tissues are firm and rigid, a sound is produced, or a peculiar sensation is felt, on dividing them resembling the cutting of thick leather. The operator now employs the index-finger to examine the opening he has made. If it feels sufficiently large to admit the passage of the hernia, he next attempts its reduction; if it prove still too contracted, the bistoury may be passed along the finger and the incision increased. The impediment to the reduction of the hernia being thus entirely removed, its replacement within the abdominal cavity is easily effected.

The following, then, are the principles upon which every step of the operation must be based: exact anatomical knowledge; the exercise of deliberate consideration and judgment; the recollection of the necessity for practical care, and for delicacy of manipulation, and of the importance of interfering as little as possible with the surrounding structures. Just so much must be accomplished as is absolutely needed and no more.

But we must revert to a few subjects merely alluded to in the preceding description of the operation.

Of opening the hernial sac.—When the anatomical relations of the hernial sac were carefully examined, it was discovered that the impediment to the reduction of the hernia was not in all instances caused by the narrow passage of the ventral

¹ A very interesting paper on these 'omental sacs,' written by Mr. Prescott Hewett, is published in the *Med. Chir. Trans.* 1844, vol. xxvii. p. 282; and another, on a case of scrotal hernia with compound omental sac, in *Isth. Trans.* vol. iii. p. 98.

orifice of the sac alone. Careful dissections showed that those structures which lie in close connection with the outside of its mouth and neck offered considerable obstruction to the retrograde passage of the hernia through those parts of the sac.

For the last hundred years surgeons of eminence have applied these anatomical facts to treatment, and many distinguished operators have dwelt upon the advantages to be derived from replacing the hernia in the abdomen without cutting open the peritoneal sac. On the grounds above alluded to, they have devised that mode of performing the operation for a strangulated enterocele called 'the division of the stricture without opening the sac,' or 'external to the hernial sac.'

The advocates of the operation believe its most favourable points to be as follows : the peritoneal cavity is not opened ; the peritoneum at the mouth of the sac is not cut ; the diseased intestine is not exposed to the influence of the atmospheric air, nor to the direct contact of the fingers of the operator ; nor is the risk of hæmorrhage into the peritoneal cavity so great, should a large vessel be accidentally cut. They consider, moreover, that the operation itself is not attended with the same amount of danger as when the peritoneal cavity is opened, its parietal reflection cut, and the inflamed bowel exposed.

The simplicity of the proceeding commends the operation highly ; for the wound inflicted is very little more than an incision through the integuments, and its advantages must have seemed paramount at a time when the dangers of the operation were exaggerated, and it was assumed that patients with strangulated hernia died from the effects of the operation itself.

Bearing in mind, however, that death occurs from the constitutional and local effects of long-continued strangulation of the bowel and its injury by forcible taxis, and because the bowel is not liberated by the operation early enough, the advantages of any particular mode of operating, especially of this one, are perhaps not quite so great as at one period many surgeons were inclined to admit. The method of performing the operation is quite a secondary consideration, in comparison with the importance of the early liberation of the bowel.

The opponents of this operation enforce their objections with the doctrine that, when the necessity arises for any cutting operation at all, the fact alone is sufficient to demand an incision into the hernial sac, in order to ascertain the cause of the impediment to the reduction of the hernia ; and that an operation for the liberation of a strangulated bowel is not complete until that viscus has been carefully examined. They also regard the risk to be great of reducing the hernia, still strangulated by adhesions, omentum, or even by the orifice of the hernial sac itself.

Next, pointing to statistical facts, and comparing the results of the two operations as performed in different metropolitan hospitals—in those where the preference is given to opening the sac in all cases, and in those in which the opposite plan is pursued—they maintain that the greatest success is obtained at those institutions where the sac is incised as a rule.

It is, however, quite clear that we are unable to collect any facts upon which to institute a safe comparison. Conclusions as to the success of the one practice or the other, based upon the results of the cases under treatment, in the hospitals, are really worthless, because the incidents in any two cases of hernia are never precisely alike, and accuracy, as to details, which is absolutely required to arrive at the truth, cannot be obtained.

We believe the dictum to be equally erroneous, when one surgeon says that in every case the sac must be opened, and another directs that it must not, except by compulsion. The proper practice consists in making a judicious selection of the cases : viz. those in which the operator opens the sac upon a fixed principle ; those in which he does not, because, according to his judgment and experience, there is no necessity to do it.

In many of the metropolitan hospitals the operation external to the sac is performed in suitable cases, upon conviction of its advantages ; and although we dare not venture to say that some of the fatal cases which have occurred after opening the sac might not have terminated differently had it not been incised, we do not hesitate

to affirm, that the untoward circumstances stated as likely to happen, when the sac is not opened, have not occurred.

Doubtless every hospital surgeon to whom the opportunity occurs of frequently operating on cases of strangulated hernia, will be guided by his own judgment as to the propriety of opening the hernial sac in every case, or of leaving it intact in selected cases. But if we may be permitted to enunciate the principle upon which inexperienced surgeons may act with safety, it would be this. In all those cases in which the surgeon would deem it safe to return the hernia by the taxis, if it were practicable, he may do the same thing after he has removed the impediment to the reduction of the hernia, by cutting those tissues lying outside the sac which are the cause of that impediment. But in those cases in which the symptoms are suggestive of an aggravated morbid condition of the bowel, and on account of which it would be improper, nay hazardous, to attempt to reduce it by the taxis—in those the sac must be opened.

In making a suitable selection of the cases for the first plan, great discrimination is therefore required. We regard those cases to be favourable for the operation in which the symptoms of strangulation have existed but a few hours, and when they have not been very severe: when the vomiting is not stercoraceous, nor the patient very prostrate; when the tumour is a simple enterocele, and when it has escaped forcible attempts at reduction. Of course no cutting operation of any kind will be attempted until after the failure of well-applied taxis to reduce the hernia.

On the contrary, the indications for incising the sac are: a long continuance of the strangulation of the hernia; inability to empty the sac completely; the persistence of stercoraceous vomiting; the prostration of the patient; the compound conformation of the tumour (it being an entero-epiplocele); and after repeated, protracted, or forcible taxis has been used.

Guided by these facts, the number of cases in which the operation of division of the impediment to reduction of the hernia external to the sac may be regarded as preferable to any other, becomes very limited. But we cannot refrain from expressing our conviction, founded upon the results obtained in those cases in which this operation has been carried out, that it is easy of performance, free from the risks attributed to it, unaccompanied by some of those accidents which occasionally occur when the sac is opened, and most favourable to the rapid recovery of the patient. It must, however, be remembered that these are select cases, and belong to a class most favourable for recovery; and we cannot deny but that they would probably be successful, even should the peritoneal sac be cut open.

Nevertheless, the inquiry suggests itself, If the hernia can be reduced with safety without opening the peritoneal cavity, why should it not be?

Of the instruments required to perform the operation. They are as follows:

An ordinary scalpel, with a single cutting edge; forceps; a grooved straight director: a grooved director, specially adapted for insertion beneath the tissues forming the impediment to the reduction of the hernia; a bistoury of peculiar construction, with which to cut those tissues; retractors.

The director and the bistoury are the only instruments requiring special notice.

The director has been constructed after a great variety of forms—straight and curved; long and short, narrow and wide; with wings or lateral projections to protect the bowel from the knife; with or without a handle affixed; with a probe-pointed end or beak, with the groove terminated, near the end, by a stop, or without such a stop. That form of the instrument invented by the late Mr. Aston Key has been employed under our observation many years with advantage; and we are able, therefore, to recommend its use. It is usually known as Key's hernia director.¹

The bistoury, used to divide the tissues which constitute the impediment to the reduction of the hernia, wherever they may be situated, has been made in a great

¹ A drawing representing this instrument may be seen in Mr. Key's *Memoir on the Advantages and Practicability of dividing the Stricture in Strangulated Hernia on the outside of the Sac*, 8vo. Lond. 1833 Drawing 1.

variety of shapes, lengths, and breadths, and usually with some contrivance, movable or fixed, to prevent its end and cutting edge injuring the intestine. It being impossible to describe every variety of the instrument, perhaps it will suffice to state the characteristics of a good one for safely performing this important part of the operation. It is desirable to have two bistouries at hand, one straight, the other curved. When the ventral orifice of the sac is deeply seated, the latter will be found very useful. In other particulars the two instruments resemble each other. The metallic part extends about $3\frac{1}{2}$ inches beyond the handle. Its sides are $\frac{3}{8}$ of an inch broad where it unites with the handle, and they gradually taper towards the end, where the breadth is $\frac{1}{8}$ of an inch. The blade terminates in a button or blunt end. At the terminal $\frac{3}{8}$ of an inch, the sides of the metal are bevelled off, and one edge is made to cut. This sharp edge should be slightly concave. All the other edges and surfaces of the metallic shaft are carefully rounded off and polished. Sir A. Cooper's hernia-knife has a cutting edge $\frac{1}{2}$ or $\frac{3}{4}$ of an inch long, beyond which extends a blunt terminal portion $\frac{3}{8}$ of an inch long. The objection we entertain to this knife relates to this long blunt beak, which must be passed into the abdomen before the cutting edge reaches the tissues which require division.

When the index-finger, of either hand most convenient to the operator, is employed as a director, its point is passed to the orifice of the sac, outside or inside; the bistoury is passed upon the anterior surface of its first phalanx, and the side of the instrument being pressed against it, lies in a depression on its soft parts. Thus the sharp edge of the knife is prevented from injuring the bowel. The end is then dexterously insinuated beneath the tissues to be cut; and as they slowly yield before it, the finger follows the direction of the knife and the operator judges of the size of the opening he is making by the facility with which his finger passes into the abdomen.

When a metallic director is used, the bistoury is gently carried along the groove of the instrument.

Of the treatment of the strangulated intestine—The primary object of every surgeon who has a case of strangulated enterocoele under his charge, should be the return of the intestine into the abdominal cavity as quickly as possible. With this object in view, 'the operation,' as it is termed, is undertaken after the failure of all other means.

But there are certain morbid states of the bowel which preclude the operator from doing this, after the liberation of the viscus from the constriction to which it was subject. The morbid conditions having been already described (p. 766), we need only briefly refer to them here, in order to direct their treatment.

Commencing, then, with the worst condition, in which the entire knuckle of the intestine in the sac is dead, mortified, or sphacelated. Before the operation, adhesions will have formed between the coils of bowel in the abdomen, as well as between them and the parietal peritonæum in the vicinity of the margins of the mouth of the sac. It would be very injudicious interference with the processes of nature to break down these adhesions. They are the result of peritonitis; and this form might be termed protective, for its effects, especially the adhesions, may possibly prevent the extension of the peritonitis, and the mischief which would certainly accrue if the contents of the alimentary canal escaped into the peritonæum.

It is sometimes difficult to find the end of the upper portion of the alimentary tube, from which the stercoraceous matter escapes; meddling with the processes of nature is not desirable, and therefore, unless the perforated viscus is easily reached, it is better to leave the parts as they are, exposed. The edges of the wound should be left free and open, in order to allow a ready escape for the contents of the bowel. In this manner an artificial anus is established. Should the open end of the gut be accessible, one, two, or more sutures may be inserted through all the structures constituting its walls, and they may be thus fastened to the integuments.

If there be a small perforation in any part of the herniated viscus, the result of disease, there are generally adhesions within the abdomen, which prevent the

extravasation of its contents into that cavity. When, therefore, the opening does not involve the whole calibre of the canal, the herniated viscus may be placed just within the abdomen; for sometimes the aperture will entirely close, even after stercoraceous matter has freely flowed through it for several days. Even a ligature may be tied around a small hole in the intestine with the best results. This treatment was successful in a case reported by Dr. P. H. Watson, of Edinburgh.¹

Should the intestine be accidentally wounded, the cut edges may be carefully drawn together by using the glover's suture, and returned just inside the mouth of the sac.

When the tissues of the herniated bowel are not perforated, but appear to be in such a morbid condition as to induce the operator to fear that their restoration to a healthy state is improbable, although just possible, the hernia may be returned if the adhesions at the neck of the sac are not strong. The late Mr. Aston Key advocated this plan of treatment. He did this upon the principle that the abdominal cavity was the place in which the injured bowel was more likely to be repaired than in any other. 'The danger of abdominal extravasation will not be increased by replacing the injured bowel at the neck of the sac; for, should sloughing of its coats ensue, the slough may be walled-in by adhesion of the surrounding peritonæum, and fecal extravasation be prevented.'² When adhesions prevent this treatment, it is better to divide the orifice of the sac slightly, and to leave the bowel in the sac. Under such unfavourable circumstances, patients occasionally recover without a fecal fistula. An interesting case of this kind is published by Dr. Watson, in the 'Edinburgh Medical Journal,' March, 1870.

In some cases the operator encounters great difficulty in reducing the hernia, even after the mouth of the sac has been freely enlarged. This depends upon the following causes:—

1. *Its bulk.*—The hernia sometimes consists of a very large quantity of intestine, which is distended with flatus: and although a portion is reducible, the reduction of the entire mass is impracticable. After the failure of these attempts, a plan may be pursued which was adopted by Mr. Tatum with complete success.³

The bowel may be punctured, and the flatus allowed to escape. Mr. Tatum used a grooved needle for the purpose; we would suggest the employment of the filiform trocar and cannula. This instrument may be obliquely inserted through the tissues of the bowel, thus forming a valvular wound.

2. *Adhesions.*—These may be *recent* and *chronic*. The latter are often formed long antecedent to the conditions for which the operation was undertaken. In the recent state the adherent surfaces are usually easily separated, whether they unite the coils of the bowel to one another, to the sac, or to the omentum. When this morbid condition happens to the viscus *in* the body of the sac, there is not much risk of the interference making mischief; but when the bowel is adherent to the mouth of the sac, the condition usually indicates an advanced morbid state of the viscus. It is an indication that nature has made preparations to prevent extravasation into the peritoneal cavity, in the event of the bowel bursting from the distension caused by accumulations in that part of the digestive tube above the hernia. Meddling with such adhesions is attended with great risk of tearing the bowel. The safest procedure is to reduce the protrusion, if possible, after having enlarged the mouth of the sac; but, even allowing it to remain in the sac, relieved from constriction, would be preferable to lacerating the bowel in the attempt to separate the adhesions, and so establishing an artificial anus. Recent adhesions to other structures may be separated with ease. Flakes of adherent lymph had better be left where found. By detaching them, the coats of the bowel may be torn; and they frequently overlie small sloughs.

Enterocœles of long standing sometimes become permanently united to a part of the sac, although very rarely. In such cases the orifice of the sac is usually large, and the chance of the bowel becoming strangulated proportionately remote. The

¹ *Edinb. Med. Journ.* July, 1869 ² *Guy's Hospital Reports*, 1842, vol. vii. p. 204.

³ See INJURIES OF THE ABDOMEN.

peristaltic action of the canal proceeds as usual in the hernia, with occasional inconvenience arising from accumulations, therein causing obstruction. Should an operation be required, two proceedings may be adopted: either the orifice of the sac may be enlarged, and the intestine left in the sac; or the adhesions of the viscera may be destroyed, and the bowel returned. The choice of these two plans might be decided by the condition of the viscus and the extent of the adhesions.¹

3. *The depth and inaccessibility of the mouth of the sac.*—That part of the sac which lies in close relation with the general peritoneal cavity is sometimes so deeply seated, that considerable embarrassment arises not only in making its orifice larger, but in returning the hernia into the peritoneal cavity when that has been done. By employing an assistant, who carefully holds the opened hernial sac by its cut edges, to draw it forwards and outwards, or from the abdomen, its mouth is more fixed and slightly stretched. This manœuvre greatly facilitates the reduction of the protrusion.

Treatment of the omentum.—Omental protrusions or epiploceles rarely require the removal of the impediment of their reduction by a cutting operation. But after the return of the intestine, in cases of entero-epiplocele, it often becomes a question what is to be done with the omentum.

The treatment is as follows: it may be reduced; left in the sac; cut off; or a ligature tied around it.

The first proceeding would be generally chosen when practicable. In some instances, however, the great bulk of omentum, or its diseased condition, necessitates a choice between either leaving it in the sac or removing it.

There are some disadvantages in leaving the omentum in the sac: the fat becomes inflamed; it suppurates, and sometimes sloughs; the healing of the wound is consequently delayed, and the after-treatment of the case thereby protracted. Usually, however, the omentum shrinks, and eventually the wound heals, but with more or less of a tumour at the abdominal aperture. This swelling may interfere with the successful application of the pad of a truss. Some surgeons, however, believe the remains of the omentum to be useful in blocking up or plugging the ventral aperture.

The removal of either the whole or a part of the protruding omentum may be effected by cutting it away at once, or by applying a ligature around it near the orifice of the sac, and leaving the portion below the ligature still attached, or cutting it off. Besides, there is the alternative of leaving the truncated end of omentum in the sac, or of replacing it in the abdomen. By the exercise of due care, omental adhesions to the sac may be safely separated, whether recent or chronic.

If the omentum be cut off, there is great risk of bleeding from its cut vessels when it is replaced in the peritoneal cavity. Even after every precaution has been taken to secure the blood-vessels, cases in which omentum has been excised have proved fatal from internal hemorrhage alone.

It has been assumed by some writers to be injudicious to tie a ligature around the omentum, on account of the untoward results which may ensue. But the reader should refer to the essay on INJURIES OF THE ABDOMEN, where he will find the good results of this plan of treatment related by Mr. Pollock, as well as the mode of applying the ligature.

By the kindness of the editor, Mr. Holmes, we are able to give the result of the practice of removing diseased or superfluous omentum, after ligature, as performed at St. George's Hospital. Of twenty cases of hernia, in which the omentum was securely tied, a few died; but the notes of the after-death examination of them show the cause of death to have been, in all cases, independent of the ligature placed around the omentum. Of eleven cases in which the omentum was allowed to remain in the sac, many recovered, although abscess and sloughing of its tissue occurred in some of them.

¹ Relating to these cases, the reader may consult *A Treatise on Obstructed and Inflamed Hernia*, by Henry Stephens.

We are informed that in no single instance has any untoward symptom been excited by the ligature of the omentum ; and that the truncated portion of omentum filling the orifice of the sac plugs it, and produces a permanent obstruction to the descent of a hernia, quite as completely as when the whole mass is left. The period occupied in the cicatrisation of the wound seemed also to be shorter in the cases in which the omentum was removed than in those in which it was not.

Cases of double hernia.—In patients suffering with a protrusion on both sides of the body, or in different regions, it is sometimes difficult to ascertain which hernia is strangulated. The surgeon must, of course, employ every means to arrive at a correct diagnosis before commencing the operation. But should he unfortunately have arrived at an erroneous conclusion, and having opened the sac of one hernia find no impediment to its reduction, nor indication of a strangulation, is he justified in cutting open the sac of the other ? Certainly. And, as a precedent, we may refer to a case in which M. Dupuytren performed a double operation, and saved the life of the patient.

A man, aged 40, was the subject of double inguinal hernia. A surgeon with much difficulty reduced both tumours. Well-marked symptoms of strangulated bowel existed, although there was no tumour at either ring. M. Dupuytren opened the right inguinal canal first, because the patient complained of most pain when pressed on that side. The sac was empty. He next opened the left inguinal canal and found a hernial sac containing an entero-epiplocele. The orifice of the sac was very deep ; it was cut ; the bowel returned ; and the patient recovered.¹

Treatment of the case after the operation.—The immediate effect of the reduction of the hernia is usually the cessation of vomiting, especially if the bowel had not been strangulated a very long time, and neither peritonitis nor hiccough had existed before the operation. After the employment of chloroform, however, the sickness and nausea induced by the anæsthetic will sometimes continue, when the treatment must be modified accordingly.

Another most striking result of the replacement of the bowel in the peritoneal cavity is the rapid relief from pain across the mesogastrium.

It is manifest that no single plan of treatment, to the exclusion of every other one, can be urged as applicable to all cases of hernia, after the liberation of the bowel. As the disease occurs at every age, in every variety of constitution, and under individual peculiarities of the most diverse kind, so strangulation of the hernia may happen with the idiosyncrasies and opposite conditions of youth and senility, strength and decrepitude, health and disease, temperance and intemperance. It must, however, be carefully borne in mind, when treating a case of this kind, that we have to deal locally with an injured intestine, and a penetrating wound of the abdominal cavity ; and that the constitutional powers of the patient are greatly reduced by continual vomiting, starvation, suffering, and alarm.

In some youthful, robust patients, the tendency to inflammatory action becomes, at an early period, strongly developed, whilst, on the contrary, in the aged and decrepit little disturbance may appear demanding interference.

The after-treatment has been conducted upon the most opposite principles. Surgeons of the highest eminence may be found amongst the advocates of the two methods, which may be briefly stated as follows :

In one class are those who administer purgative medicines almost immediately after the operation, and persist in their continuance 'until the canal is completely unloaded.' Calomel, extract of colocynth, sulphate of magnesia, and castor-oil, are given by the mouth, or aperient enemata injected into the rectum.

Another class, relying almost entirely upon the restorative powers of nature and the influence which repose exerts on the reparation of injured tissues, depends upon diet and, when required, opium.

In selecting one of these plans of treatment for adoption, we give the preference to the last, since it seems to be most suitable to the majority of the cases occurring in hospital practice. In many cases we have allowed the patient to recover without

¹ *Leçons orales*, edit. 1832, t. i. p. 583.

giving any medicine whatever ; great care, however, being taken that a mild and farinaceous diet, with milk, be only sparingly taken.

This necessity for repose, writes Mr. Key, in an injured state of the bowel, it would be well to bear in mind, after the operation for strangulated hernia. The bowel is gorged by the strangulation, bruised by the taxis, as it is too often practised, or inflamed by long incarceration in the sac. An intestine in such a condition cannot but be injured by an early administration of purgatives, which irritate and inflame the bowel, or exhaust what little remains of vital energy. After the operation, some time for repose should be allowed before the bowel is called into action: the surgeon's anxiety to procure stools should yield to the evident necessity for time being allowed for the restoration of the natural powers of the injured bowel.¹

Great advantage is sometimes derived from the effects of thirty drops of the tincture of opium, which may be given with a little brandy-and-water, or camphor-mixture, soon after the operation.

The bowels are often relieved spontaneously a few hours after the reduction of the hernia ; but when they are obstinately inactive, the question arises of the necessity of giving aperient medicines. We have embraced abundant opportunities of comparing the advantages to be gained by the use of purgatives, and by abstaining entirely from their employment. We give the preference to the latter plan, but if the lower bowel becomes loaded, and any discomfort arises from accumulations therein, an enema of warm water, or gruel with common salt or a little castor-oil, or even sweet oil, mixed with it, produces the desired result. Cases under our treatment have progressed favourably, and even the wound has healed, before the bowels have been relieved, and not the slightest trace of inconvenience occurred from the constipation.

When there is much tenderness on slight pressure on the abdomen, in the neighbourhood of the wound, the local application of leeches is of great service, and it may be repeated as often as required, but in relation to the powers and condition of the patient.

If acute peritonitis be developed, the treatment must be in accordance with the ordinary rules for the treatment of that disease.

Stimulants are often required soon after the operation, and should be given in small quantities. Indeed it is a rule which requires to be enforced, that all aliment must be given in very small quantities, and repeated at short intervals.

If thirst be distressing, pieces of ice placed in the mouth afford great comfort.

Treatment of the wound.—The structures which have been cut and disturbed by the cutting operation should be placed in relation to each other, and the divided edges of the integuments brought together by sutures. The number required may be left to the discretion of the operator, but no more need be used than sufficient to keep the upper two-thirds of the wound united. For it is always advantageous to leave an opening at the lowest end to allow of the escape of blood and discharges. A piece of wetted or dry lint may be laid over the incision, and a pad of folded lint is adjusted over it with a bandage by some surgeons. However, a bandage is not required in every case, nor is it on any account essential.

If, during the subsequent progress of the case, the connective tissue in the wound, the omentum, or the hernial sac should inflame, the appearance of the integument soon betokens that union by adhesion is hopeless. In that case the lowermost sutures, or all of them, must be removed, and the treatment to be adopted need not differ from that commonly employed in every inflamed, suppurating, or sloughing wound. The grand point is to keep a channel open for the free escape of the discharges.

The prognosis of a case of strangulated hernia.—Reflection upon the facts already described will enable the surgeon to form a very nearly accurate prognosis of a case of strangulated hernia. But in order to concentrate the attention of surgeons upon those incidents which more especially cause a fatal termination, we must briefly

¹ *Guy's Hospital Reports*, 1842, vol. vii. p. 263.

recapitulate the most important morbid conditions which call for special observation.

1. The condition of the tissues of the herniated viscera, and especially of the intestine. Their morbid state is too frequently produced by violence in the use of the taxis, by long-continued constriction, or very tight strangulation of short duration. In such cases, then, the prognosis is usually unfavourable on account of the destruction of the portion of the bowel injured, or of its inability to repair the damage inflicted upon it.

2. The morbid state of the peritonæum, visceral and parietal, and of the tissues of that portion of the track of the alimentary canal between the stomach and the hernia. The existence of peritonitis antecedent to the liberation of the bowel cannot be regarded in any other light than as a symptom of grave significance. Associated with it, the alimentary canal above the hernia is usually greatly distended, and its contractile fibres appear to lose their function. These circumstances add to the unfavourable prospects, and lessen the chances of recovery in a very marked degree.

3. The impaired functions of the nervous system. Many patients sink away in the stage of prostration alone. This state of the nervous system is induced by long-continued vomiting, starvation, pain, suffering, exposure, neglect, journeying, purgative medicines, some medicated enemata, the hot or warm bath in some instances, and other measures supposed to facilitate the reduction of the hernia by the taxis. When great prostration, therefore, precedes the reduction of the hernia, it must be regarded as a most unfavourable indication.

4. Neither should we overlook the chronically morbid states of the viscera of the thorax and abdomen, irrespective of the hernia, so commonly existing in the class of persons admitted into our hospitals. Over the influence of these conditions, however, we can exert but little control, although they form an important element in prognosticating the issue of any case.

5. All these conditions are also influenced by the age of the patient, social habits, general cachexia, and individual idiosyncrasies—features in a case to which due attention must be given.

Now the lesson that we learn from the study of those morbid states which bring about a fatal termination is this: To return the herniated viscus into the abdomen as quickly as possible; to accomplish this with the utmost delicacy of manipulation consistent with the requirements of the case; to distinguish carefully between those cases in which no delay is admissible in liberating the bowel without the loss of a moment, and those in which some means are justifiably employed to assist the taxis. By acting thus energetically upon sound principles; by remaining at the bed-side of the patient, or at least not leaving the case until the risk of danger is averted by reducing the intestine, the surgeon may hope to rescue from death a very large majority of the cases of strangulated hernia.

The high mortality arising from strangulated hernia is an opprobrium upon the medical art which cannot be removed by any amount of skill or dexterity displayed by the operating surgeon. The risk of the operation, the mode of its performance, and the subsequent treatment of the case, are merely secondary considerations when compared with the treatment to which the patient is subjected before the operator is called upon to perform his part. All matters relating to the operation only have, perhaps, reached perfection; but it would really appear, from the condition in which patients are sent into the hospitals to be operated upon, that the greatest amount of ignorance prevails of the principles upon which an irreducible hernia should be treated.

HERNIA.

PART II.

SPECIAL KINDS OF HERNIA.

THE following classification of abdominal ruptures is arranged with regard to the anatomical divisions of the abdomen in which they appear :

- | | | |
|--------------------------|---|---|
| I. In the EPIGASTRIUM | { | 1. Diaphragmatic. |
| | | 2. Epigastric. |
| II. In the MESOGASTRIUM | { | 1. Ventral (also in other regions). |
| | | 2. Umbilical. |
| | | 3. Lumbar. |
| | A | 1. Above Poupart's ligament ; inguino scrotal ; or labial. |
| | B | 2. Below Poupart's ligament ; femoral. |
| | C | 3. Through the apertures of the pelvis ; in front —beneath the ramus of the pubes, obturator. |
| III. In the HYPOGASTRIUM | | 4. In front—beneath the arch of the pubes, perineal. |
| | | 5. Pudendal. |
| | | 6. Vaginal. |
| | | 7. Behind through the ischiatic notch, ischiatic. |

HERNIE IN THE EPIGASTRIC REGION.

Diaphragmatic hernia.—Of these cases there are three kinds :¹ first, that in which a part of the diaphragm muscle becomes stretched in consequence of a loss of tone, and is pressed up into the thoracic cavity by the contents of the abdomen ; secondly, that in which, in consequence of congenital defect, some of the viscera pass through the aperture into the thorax ; and, thirdly, when some of the abdominal viscera pass into the chest through the natural apertures in the diaphragm, which have become enlarged.

Epigastric hernia escapes in the angle bounded by the cartilages of the first false ribs, the apex of which corresponds to the appendix of the xiphoid cartilage. M. Malgaigne has seen an infant with a tumour in this region which swelled up every time any effort was made with the abdominal muscles. The sac of this hernia is generally more movable than that of an umbilical, and the mouth through which the hernia enters it is usually large. The reduction of the protrusion is therefore easily effected. A suitable bandage is required to prevent the escape of the hernia, which sometimes consists of a portion of the stomach, or arch of the colon and omentum.

¹ Exclusive of cases in which the abdominal viscera pass into the chest through a laceration in the diaphragm. Such cases are treated of under INJURIES OF THE ABDOMEN.

HERNIA IN THE MESOGASTRIC REGION.

Ventral hernia.—Of this hernia there are two kinds : first, those which occur at the linea alba ; and, secondly, those which pass through other parts of the parietes, except the so-called rings.

Those of the first kind usually escape in the linea alba between the umbilicus and the pubes. They are produced as the consequence of general relaxation and stretching of the fibrous tissue in the middle line of the abdominal walls after they have been greatly distended during pregnancy or ascites. We have seen hernia consecutive to an abscess in which the pus had made its way through at the linea alba. This kind of hernia is more common than the second, which escapes through any part of the anterior or lateral walls.

The usual indications of a rupture accompany these kinds also ; the chief risk of an error of diagnosis arises when chronic abscesses, cysts, or fatty growths exist in the parietes. If the hernia be reducible, the surgeon would not be likely to fall into error ; and if not, the history of the case, with a careful manipulative examination, will enable him to form an accurate diagnosis.

Umbilical hernia.—By this term we understand that kind of rupture which escapes from the abdominal cavity, either through the umbilical ring in the fetus, or by an aperture formed at a later period of life in consequence of a separation of the fibres of the linea alba in the umbilical region. (See fig. 167, p. 817, in which a small one is delineated.)

The synonyms are, *exomphalos*, *omphalocele*, or, in common language, ruptured navel.

It is developed at all periods of life, and in both sexes. Most commonly observed in infancy, it forms a protrusion either before or soon after the separation of the umbilical cord. In youth it is rarely developed, provided that the umbilical aperture has been once well closed. As years advance, it is more frequent, especially in females, and particularly so in persons disposed to obesity.

The hernial sac is always an acquired formation in this rupture ; that is to say, there is not any peritoneal extension at the umbilical ring, in fetal life, analogous to the inguinal vaginal process of the peritoneum. Nevertheless, writers have been long accustomed to divide this hernia into the congenital variety, or that which is so common in infants ; and the acquired, or that variety which is developed in after-life.

In infants the protruding viscus pushes before it that portion of the parietal peritonæum lying immediately behind the aperture in the linea alba, through which the umbilical vessels enter the abdominal cavity. The hernial sac is thus formed before the closure of the ring is effected, and may pass into the connective tissue of the cord itself, before that structure has separated. We have seen such a case in which the integuments covering the sac sloughed. Rather later, after the separation of the cord, the hernial sac may be protruded in consequence of the umbilical aperture remaining imperfectly closed when it is covered only by the integuments. In youth, a rupture may be developed by escaping through a partially closed ring, which, by continued pressure, it dilates, unless precautions be taken to prevent it. And, in adult life, the fibres of the linea alba become separated by stretching or yielding to the pressure from within, and the rupture escapes at the site of the once closed ring, or in its immediate vicinity. The coverings of the hernial sac are generally very thin, and often inseparably united together. They consist of the integuments ; some fat, which, however, is not often in proportion to the thickness of the layer over the other regions of the abdomen ; and the delicate internal abdominal fascia. The body of the sac is usually very delicate, but it is rather stronger near and at its orifice, around which part the tissues outside of it form a very firm, resisting, unyielding band. The mouth of the sac is often large in proportion to the bulk of the protrusion. The relation which it bears to the tumour when the protrusion is large should be carefully studied. As the bulk of the hernia increases, it does not

spread equally around the ventral aperture upon the anterior surface of the abdominal walls, but it descends towards the symphysis pubis. In some cases it happens that the transverse diameter of the tumour is greater than the vertical¹; and occasionally its configuration is so pyriform that the tumour seems to be suspended by a peduncle or stalk. At other times its base is nearly as large as its body; and, again, we may see an almost sessile tumour which, when elevated, is attached by a small stalk, thus resembling a mushroom in shape.

Various organs of the abdomen are found in the sac of an umbilical hernia; very frequently the omentum, the stomach,¹ portions of the small intestines and of the large. When the disease has been neglected, we have seen nearly the whole of the intestinal canal in the sac enveloped by omentum. The last-mentioned organ sometimes becomes firmly united to the sac; and when bands or septa are thus produced within it, the intestines may become entangled by them. The omentum likewise becomes hard and contracted, forming masses within the sac which sometimes give rise to difficulty in diagnosis.

This rupture begins by forming a small soft projecting ovoid tumour at the navel. Gentle pressure with the finger pushes something into the abdomen, and a small hole is then felt, with very sharp, rigid edges. Directly the finger is removed, the skin either remains relaxed or flabby in the fossa of the navel, or it is slowly projected forwards, and reappears in the same bold relief. If the progress of the disease be not arrested, the protruding viscus descends lower and lower, so that the broadest part of the tumour lies below the mouth of the sac. A curious example of congenital umbilical hernia, coupled with malformation, was shown by Dr. Gibb at the Pathological Society, and in the same volume of the 'Transactions' there is a description of a case of triple umbilical hernia which contained portions of the stomach, duodenum, jejunum, ileum, omentum, and ductus communis choledochus.²

Treatment when reducible.—Should there be any disposition to a protrusion at birth, or soon after, the simple application of a bandage is not merely palliative, but materially tends to the cure of the case. In infancy, after the separation of the cord, the protrusion may be prevented by fixing a piece of cork over the umbilical ring. It should be circular, about one inch in diameter, slightly convex on both surfaces, and covered with soft leather. With adhesive plaister to retain it in its proper place, and a bandage encircling the abdomen, but not violently compressing it, this plan is sure to effect a cure. When the protrusion occurs in an adult, a suitable truss or bandage must be employed, with a view to prevent the dilatation of the sac and the increase of the tumour. If a large irreducible hernia has to be treated, a suitable appliance is required.

The radical cure of this hernia has been successfully effected by an operation performed by Mr. Barwell, on three patients, at the respective ages of six months, fifteen months, and eight years.³ It is, however, open to further inquiry, how far any cutting operation is justifiable in infancy, as so large a proportion of cases are curable by bandages or trusses. Mr. H. Lee states that he has cured cases by inserting needles through the sac, after carefully reducing its contents, and keeping the surfaces in close contact by twisting a ligature over them. Mr. Wood makes use of rectangular pins and the wire suture.

Mr. C. Heath, having been called on to operate in a case of strangulated umbilical entero-epiplocele, after having returned the bowel, dissected the sac from its attachments; and having passed a ligature through its base and the omentum, cut them off. The patient recovered; and when the report was given to the Pathological Society there was not then any hernial protrusion.⁴ But we are at a loss to understand how the opening in the linea alba was closed by these means; and therefore until it can be shown that this has been accomplished, we should not recommend the adoption of this measure.

¹ A very interesting case is related by Mr. Moore, in the *Med.-Chir. Trans.* vol. xlv. p. 181.

² *Trans. of the Pathological Society of London*, vol. vii. pp. 216, 220.

³ *The Lancet*, 1861, vol. ii. pp. 419, &c.

⁴ *Transactions of the Pathological Society*, vol. x. p. 131.

Cases of umbilical hernia offer remarkably well-marked examples of that condition termed obstruction from accumulation of stercoraceous matter, and patients are constantly subject to severe constitutional disturbance arising from this cause alone, and not from positive strangulation of the bowel. We should not, therefore, be in a great hurry to operate in these cases; for after a free administration of aperient enemas, the bowel becomes unloaded of its contents, and evacuations from the alimentary canal are obtained.

The operation.—An incision should be made in the mesian line of the body, commencing about two or three inches above the upper border of the mouth of the sac, and continued downwards upon the sac as far as may be requisite. The smaller the opening by which the surgeon can remove the impediment to the reduction of the hernia, or liberate the bowel from constriction, the better; and when it can be accomplished without opening the peritoneal sac, it is desirable to do so. Great caution is necessary whilst cutting the different coverings of the sac; and should it be necessary to cut the tissues forming its orifice, the incision should extend upwards in the same line as the first.

Hernia in the loins.—Lumbar hernia has been described by several surgeons. These protrusions arise after contusions of this region, or perhaps after lacerations of the abdominal muscles in the part, as well as from relaxation of the tissues. In the third 'Bulletin des Travaux de la Société de Médecine de Marseille,' Dr. Chapplain¹ relates the case of a man, aged 60, who, after being squeezed between a wall and a carriage, found in his loin a tumour between the crest of the ilium and the last rib. It appeared at first like a chronic abscess, but the presence of intestine was easily ascertained. Mr. Kingdon has seen a case of this kind. The bowel protruded just above the crest of the ilium at its highest point, about three inches from the spine, just where the quadratus lumborum and abdominal muscles meet. The man was 54 years old, tall and thin. He suffered with hæmoptysis and emphysema of the lungs.

HERNIA IN THE HYPOGASTRIC REGION.

Inguinal hernia is the most common kind. The statistics of the City of London Truss Society prove this; for rather more than two-thirds of the total number of applicants of both sexes for trusses to support every description of hernia, were afflicted with inguinal ruptures of one kind or the other.²

Of inguinal hernia the following varieties are described: the oblique or external, and the direct or internal. The terms external and internal have reference to the course taken by the internal epigastric artery in relation to the orifice of the hernial sac. In the oblique kind, the mouth of the sac is situated to the outer or external side of this artery; in the direct, this important part of the sac is placed to the inner side of the same vessel.

There are also varieties of the oblique kind named according to the situation of

¹ *L'Union médicale*, 1862, vol. i. p. 157.

² TABLE B.—*Showing the proportions between inguinal and femoral hernia in both sexes at different ages.* (Constructed from Kingdon's tables, 1863) (G.)

Ages	Inguinal		Femoral	
	Male	Female	Male	Female
1 to 10	2,435	249	23	38
20 to 40	2,054	322	130	432
40 and upwards . . .	2,154	128	144	278
	7,543	699	306	748

This table shows—1. That inguinal hernia is most common. 2. That in females femoral and inguinal hernia occur in about equal proportions. 3. That femoral hernia in the male is the least common of these kinds.

the protrusion; thus the tumour is called a 'bubonocoele' when the hernia has passed the internal inguinal ring, but has not protruded at the external, when, in fact, it is retained in any part of the inguinal canal. It is called 'scrotal hernia, or oscheoceale,' when it has passed through the external abdominal ring, and is therefore in the scrotum.

We propose the following anatomical classification of the varieties of oblique inguinal hernia.

1. Into the vaginal process of the peritonæum (the congenital hernia of Haller, and subsequent writers).
2. Into the funicular portion of the vaginal process of the peritonæum.
3. Scrotal, the sac being thrust into the tissues of the scrotum.

Of inguinal hernia in the male.—This species escapes from the abdomen, *above* Poupart's ligament, through the internal and external inguinal apertures or abdominal rings. There are two varieties, the *oblique* and the *direct*.

Oblique inguinal hernia, having passed through the internal inguinal ring, lies in

FIG 163.—Double Inguinal Hernia.

On the man's right side the protrusion has passed through the inguinal canal, and is just entering the scrotum. On the left side it is called bubonocoele. The outline of Poupart's ligament, below the swelling produced by the protrusion, is distinct.

the inguinal canal. Pursuing the oblique direction of this canal, it points at the external inguinal ring, emerges and enters the scrotum, into which it descends. The mouth of the hernial sac is situated to the outer side of the internal epigastric artery, whilst its neck and body are usually in front of the structures composing the spermatic cord. But in rare cases these organs are divided; sometimes the blood-vessels pass over the tumour, the vas deferens behind it, and *vice versa*; or they are attached to the sides of the tumour. The relative positions of the hernial tumour and testicle differ. The variable site of this organ depends upon congenital defect, and hence in some cases the testis cannot be distinguished from the tumour produced by the hernia. However, in the majority of cases, the testicle is situated at the posterior and inferior region of the scrotum; more rarely, it may be detected at the front of the fundus of the tumour. An endeavour should always be made to ascertain the site of this organ, in every case of inguinal hernia, and under all circumstances.

The coverings of the sac of an oblique inguinal hernia are formed by the tissues of the region in which it lies. To expose the sac of a bubonocoele, it is necessary to divide the integuments of the groin, the aponeurosis of the external abdominal

oblique muscle, and the internal spermatic fascia. Some of the fibres of the free edges of the internal oblique and transversalis muscles are observable along its upper border, and some fibres of the cremaster muscle skirt its lower edge. To reach the sac of a scrotal hernia, we must divide the integuments of the scrotum, including the dartos, the fibres of the cremaster muscle, often strongly developed, and the internal spermatic fascia. This last-named fascia is the delicate membranous extension of the internal abdominal fascia along the spermatic cord.

The mode of development of the sac of an oblique inguinal hernia differs essentially in respect of the age of the individual in whom it takes place. Thus in infancy, youth, and early manhood, the disease is usually dependent for its existence upon a congenital imperfection. To this circumstance is due the persistence of a serous canal, or sheath, in direct communication with the peritoneal cavity, through the mouth of which a portion of omentum or of bowel may enter, and thus form a hernia at any period of life. On the contrary, in adult life, the hernial sac is a secondary structure, a distinctly new formation. Its development is slow; its progressive stages may be traced; and, although a prolongation of the parietal peritoneum, its existence is due to a morbid action, which allows displacement or stretching of this serous membrane.

FIG. 164.

Hernia into the vaginal process of the peritoneum.—The development of these two very different kinds of sacs has been already described (see pp. 754, 757), in considering the causes of hernia, and at the same place the reader will find the reasons which induce the author to prefer the designations of ‘hernia into the vaginal process’ and ‘into the funicular portion,’ to those of ‘congenital’ and ‘infantile,’ formerly in use. There also the natural varieties found in the condition of this process are described.

Under abnormal conditions, the following states of this sheath are found :—

1. The whole length of the canal remains open.
2. The entire canal may remain open, and an annular constriction of its walls take place between the external abdominal ring and testis.
3. The tunica vaginalis propria testis is perfected, becoming now a closed sac, but a canal exists as far as the testis.
4. The abdominal orifice is completely closed, but a canal below this exists.

The diagrams are intended to illustrate the congenital conditions of the vaginal process of the peritoneum. The serous canal is represented cut open vertically and viewed from the front.

Fig. 164, A. The tubular process of the peritoneum is open from the general peritoneal cavity to the fundus of the scrotum, at which part the testis is situated. This gland, however, may be fixed at different sites.

Drawings representing this imperfection may be found in the following works :

Camper, 'Icones Herniarum,' tab. x. fig. 3; Hunter (John), in 'Medical Comm. pt. i. chap. ix. ; and in Palmer's edit. of the 'Works of J. Hunter,' plates xxy. xxvi. For numerous references to books on this subject, refer to 'A Treatise on Ruptures,' by W. Lawrence, F.R.S., 5th edit. 1838, p. 564.

The variety of hernia developed in consequence of this imperfection is the hernia congenita of Haller and subsequent authors.

Fig. 165, A. In this figure the vaginal process of the peritonæum is open, as in the last imperfection ; but a contraction has taken place at the point above the testis.

This imperfection is demonstrated by a preparation in the Museum at Guy's Hospital, No. 2368 ; and a drawing from a case reported by Sir Charles Bell, in the 'London Medical Gazette,' 1828, vol. i. p. 485.

Examples of hernia into a vaginal process of this kind are noticed by Scarpa ; see Wishart's translation, 'Memoir,' ii. § 10. A drawing of a similar case may be seen in the work by Sir Astley Cooper on 'Abdominal Hernia,' the 2nd edition by Mr. Key, pl. ii. fig. 2. Another is related by Mr. Lawrence in his work on 'Ruptures,' as before, p. 574, and I have myself operated upon cases of this kind in young men. A large hernial sac with this remarkable condition may be examined in the Museum of the Royal College of Surgeons of England, No. 1343.

Fig. 164, B. This diagram shows the division of the vaginal process of the

FIG. 165.

peritonæum, into the inferior testicular vaginal process ; and the superior funicular vaginal process, at the ventral end of which a communication with the abdomen remains, as on the other side.

This imperfection is delineated by Camper. In the work 'Icones Herniarum,' folio, 1801, plate x., he contrasts it with that one represented in fig. 164, A. The drawing was made from the dissection of an infant, in 1759. Seiler also gives a figure to illustrate a rather more contracted state of this part of the vaginal process, in a work entitled 'Obs. de Testiculorum ex abdomine in scrotum descensu, &c.' More recently, M. Malgaigne has described the frequency of hernia in association with this imperfection, 'Leçons clin. sur les Hernies,' Paris, 1841 ; and in 'L'Union médicale,' 1854.

Examples of hernia into the funicular portion of the vaginal process of the peritonæum occur very commonly in children, and a preparation of a hernial sac, originating with this defect, is preserved in the Museum of the Royal College of Surgeons, No. 1328.

Fig. 165, B. In this diagram the vaginal process is represented as a tube passing down in front of the spermatic cord and testis. The ventral orifice has been closed above or nearly so.

This is the condition of the vaginal process of the peritonæum described by Mr. Hey, in which he 'found that the tunica vaginalis was continued up to the abdominal ring' ('Practical Obs. in Surgery,' 3rd edit. 8vo. 1814, p. 227).

I suspect that it is this imperfection of which preparations exist in museums, described as 'a congenital hernial sac with the mouth obliterated,' when unaccompanied with a history that the man from whom it was removed had ever been ruptured.

Associated with congenital persistence of the vaginal process of the peritonæum, the testicle of the same side as that on which the defect occurs frequently occupies an abnormal situation.

When in its normal site at the lower part of the scrotum, it cannot always be distinguished from the hernial protusion which occupies the same serous sac as this organ and overlies it. But, although this region should contain a hernial tumour, the testis may not have reached the scrotum at all.

The situations in which it is then found are as follows :

1. Within the abdomen ; the vaginal process extending into the inguinal canal, but not reaching further than just through the external abdominal ring, or into the upper part of the scrotum.
2. Fixed in the inguinal canal out of the reach of manipulation ; whilst the serous canal, passing into the scrotum, forms a sac for the reception of a hernia.
3. Immediately outside the external abdominal ring at the upper part of the scrotum ; in which state, when a hernia descends, it passes in front of this organ into the scrotum, even as low as its fundus.
4. When the testis is in the perinæum. A defective development of one or even both sides of the scrotum is associated with the cases of deformity above described which may lead the surgeon to discover an abnormal position of the testis ; a fact of great importance in the treatment of these cases of hernia.

Tabular view of the abnormal conditions of the vaginal process of the peritonæum, deviations from the normal situation of the testis, and the relative position of the hernia.

Hernia into the vaginal process of the peritonæum :

1. The vaginal process continuing open and common to the cord and testis. (Fig. 164, A.)

The testis may be situated—

- a*, in its normal site at the fundus of the scrotum ;
- b*, just outside the external abdominal ring, or between its pillars ;
- c*, within the inguinal canal ;
- d*, within the abdomen.

N.B. In *a*, *b*, *c*, the hernia is generally in contact with the testis ; in *d*, it is not.

2. The vaginal coverings of the cord and testis communicating by an aperture. The testis in the scrotum.

N.B. The hernia may or may not pass through this aperture, and is therefore sometimes but not always in contact with the testis. (Fig. 165, A.)

3. The vaginal covering of the cord only being open. (Fig. 164, B.) The testis in the scrotum.

N.B. The hernia is never in contact with the testis.

APPENDIX.—Additional sacs, or prolongations and extensions of the vaginal process within the abdominal walls.

Concurrent with these instances of misplaced testis are some of those complicated cases of hernia which arise from varieties in the configuration and anatomical disposition of the hernial sac. In a majority of the cases in which the hernial sac follows any very unusual direction, the hernia is found to occupy the same sheath as the testis, or a portion of that sheath—a sufficient proof of the precise nature of the hernia and of the cause of its development, if any be required. Several cases are recorded in which a sort of second sac or offset from the vaginal process of the peritonæum extended between the structures composing the abdominal walls.¹ Hence the terms

¹ *Guy's Hospital Reports*, 1861, p. 270.

intraparietal,' 'ascending, or intermuscular,' and 'interstitial,' have been applied to his variety of hernial sac. Belonging also to this category are the cases termed *hernie en bissae* by French writers. These cases form two classes :

- 1st. Those in which the sac extends into the anterior abdominal wall.
- 2nd. Those in which it extends into the inferior walls.

In the first class, the sac extends upwards from the inguinal canal in front of the internal abdominal fascia, and behind the aponeurosis of the external abdominal oblique muscle. It may take a course directly upwards; outwards, towards the crest of the ilium; or inwards, towards the rectus muscle and umbilicus.

If the sac has passed through the external abdominal ring and cannot enter the scrotum, it may ascend in front of the aponeurosis of the external abdominal oblique muscle, lying between it and the integuments; and when the hernia protrudes, it forms a tumour in the groin above and parallel with Poupart's ligament. An example of this rare variety is quoted by Scarpa,¹ and another case has been recorded by Dr. Fano.²

In the second class, the sac extends into the iliac fossa and rests upon the iliacus muscle, between the internal abdominal fascia and peritonæum; or directing itself inwards, it passes behind the horizontal ramus of the pubes, and reaches the side and front of the urinary bladder.³

Hernia into the funicular portion of the vaginal process of the peritonæum.—When the surgeons of the last century discovered that a hernia could pass into the vaginal process of the peritonæum, and there lie in contact with the testicle, they appear to have been content with this fact, and, without further research, to have assumed this variety to be the only form of hernia dependent for its origin upon non-closure of the ventral orifice of this canal, or defective obliteration of the funicular part of the vaginal process of the peritonæum. Thus many writers acknowledge the fact that an infant may be the subject of a scrotal hernia, and, after detailing such a case, they add, 'but not congenital'; implying by that expression simply the anatomical fact that the hernia is in a distinct sac, and thereby separated from the testis, in the same manner as it occurs in the adult. The term suggested in this essay precludes an erroneous view of those varieties of hernia which originate in congenital defect of the coverings of the testis and spermatic cord, and renders the disease in the infant and in youth much more easy of comprehension.

The reader should recall to mind the previous statements relating to the descent of the testicle, and the development of the tunica vaginalis propria testis out of the inferior termination of the vaginal process of the peritonæum. For surely there cannot be a tunica vaginalis propria testis developed so long as a canal exists along which a hernia may descend and touch the testis. Herein consists the deficiency; in this anatomical fact lies the defect. But when the testis is enveloped by the two layers of the serous membrane, the visceral and parietal, whereby the cavity of the tunica vaginalis testis is formed, in its own proper vaginal sheath, and is entirely shut off from every protruding viscus, there may yet remain the funicular portion of the vaginal process of the peritonæum communicating with the abdomen at the internal abdominal ring. Into this canal, termed the tunica vaginalis propria funiculi, a hernia may protrude, and the canal thus becomes converted into a hernial sac; quite as much 'congenital,' too, as the variety ordinarily characterised by that term, for it is dependent upon a congenital defect, viz. the non-closure of the abdominal orifice of the canal, and its continuation in front of the spermatic cord as far as the testis and its vaginal sheath. This variety is now distinguished as hernia into the funicular portion of the vaginal process of the peritonæum.

In the new-born infant, or at a later period, some weeks or months after birth, it is not at all uncommon to see males with a hernial protrusion occupying the

¹ *Treatise on Hernia*, translated by Wishart, 1814, 8vo. p. 171.

³ Cases by Dr. Parisc, in *Mém. de la Soc. de Chir. de Paris*, 1851; *Mém. sur deux variétés nouvelles de Hernies*.

inguinal canal and scrotum, but entirely separated from the testis, which is normally situated, at the fundus of the scrotum.

M. Malgaigne was, I believe, the first surgeon to notice this variety of hernia, and to point out its origin, anatomical relations, and distinctive features. It is exceedingly common. Carefully instituted examinations lead us to conclude that it is nearly as frequently met with as the ordinary variety last described; but, from the fact of its having been confused with the scrotal hernia of the adult, very little attention has been bestowed upon it. The diminutive size of the testis has also led to its relative situation, as regards the hernia, being wholly overlooked and neglected; for cases which we have ourselves examined have generally been regarded as of the ordinary kind, termed 'congenital,' and not worthy of further consideration. In the earlier periods of life, the distinction is not, perhaps, of primary importance; but the recognition of this variety in youth and adult life becomes a necessity of great moment in some instances, not only in reference to correct diagnosis, but also with respect to the judicious treatment of the case.

In these cases, the hernia being enveloped by a peritoneal sac, the pathologist must admit one of two explanations of its development: either that the parietal peritonæum of the abdomen was suddenly pushed downwards before the hernia to form its sac; or that a serous canal existed continuous with the peritoneal cavity, which became converted into the hernial sac. The last explanation, being strictly in accordance with anatomical facts, appears to me to be the one which the morbid anatomist will adopt.

The congenital patulence of the funicular portion only of the vaginal process of the peritonæum is capable of proof by anatomical examination, and there is no more reason to question its remaining so during the later periods of life, than to dispute the fact of the occasional unobliterated state of the entire length of the vaginal process to the fundus of the scrotum in adult life. We are able to adduce abundant facts to prove the development of hernia in such cases, if space permitted.

In advancing adult life, the orifice of the hernial sac still maintains its original relations to the internal abdominal ring, and especially its depth. Under these circumstances, a hernia having existed many years, the abdominal rings are not approximated, but remain widely separated. A man, forty-five years' old, was operated upon by myself on account of strangulated oblique inguino-scrotal hernia, with which he had been afflicted since boyhood. This was the first time he had found any difficulty in returning the protrusion. The orifice and neck of the sac were deeply seated; that is, the index-finger was passed along the inguinal canal to reach the abdominal orifice of the sac. It did not require division, but was sufficiently large to allow of the reduction of the hernia after the sac had been opened, and a large quantity of serum had escaped. His case terminated successfully. The testis was at the fundus of the scrotum, and separated from the contents of the hernial sac.

The next question relates to the frequency of these varieties of hernia into the vaginal process of the peritonæum.

After making inquiry of patients afflicted with inguino-scrotal hernia for many years, we were much surprised to find that so many of them stated that the protrusion occurred suddenly, and was first observed when the dimensions of the scrotum were increased by the presence of the hernia. Another circumstance also attracted attention. Robust, healthy, and well-developed men, of middle age, asserted that the rupture first ascended when they were about twenty years old—a circumstance nowhere specially alluded to; but it appears to be a very common occurrence. When discussing this matter with friends, and stating this fact, they have suggested that working-men might not be very accurate in their statements, and that, being habitually thoughtless of their persons, no dependence could be placed upon their assertions. This objection has had its due consideration and weight in our inquiries, and we have, therefore, only referred to recent cases, or accepted the accounts afforded by those patients who seem to possess a fair average intelligence and might be presumed to give reliable information concerning the subject of inquiry. During the

two years 1859 and 1860, forty-four patients, suffering more or less from inguinal hernia, were admitted into the wards of Guy's Hospital. Among them were twenty-six cases of hernia into the vaginal process of the peritonæum; and of these, twelve had the testis and hernia in contact (the hernia congenita of Haller), whilst in the remaining fourteen the hernia occupied the funicular portion of the canal, and was separate from the testis. In several patients the hernia was developed suddenly, and reached the scrotum at once, the first time it was observed, even in adult life, the men being robust, and well-developed. The respective ages of the patients, at the time they came under examination, varied between fourteen months and forty-seven years.

Pott wrote, nearly a hundred years since: 'Ruptures attended with that particular circumstance which brings them under the description mentioned in the title, are said to be very rare; but from what I have observed, both in the living and in the dead, I am inclined to believe that they happen much oftener to adults than they are suspected to do.'¹

To demonstrate, perhaps even more satisfactorily, that a large proportion of the cases of inguinal hernia is developed at a very early period of life, we may refer to the Reports of the City of London Truss Society, so industriously drawn up by Mr. Kingdon.

The total number of males applying at the Society during the years 1860 and 1861, whose ages were ascertained at the time the hernia was first observed, amounted to 7,543; of these, 3,963, or 383 more than half, had reached only thirty years of age. Thus it appears certain that inguinal hernia is developed very frequently before thirty years of age.

This statement, which may be accepted as correct, is fully supported by reference to the table I have arranged from the Report of the City of London Truss Society (see table, p. 718). By this it appears that inguinal hernia occurs very frequently during the first twelve months after birth. This happens in consequence of the congenital persistence of the canal of the vaginal process of the peritonæum. Its frequency then diminishes to puberty, after which period the cases rapidly increase to the completion of thirty years of age.

Taking periods of ten years, or decades, the frequency of inguinal hernia at different ages is well seen (see table, p. 796). It is remarkable that the first decade contains the largest number of cases, and next the third or that between twenty and thirty years of age. From this period of life the cases decrease in a rapid ratio.

Hour-glass-shaped contraction of the sac of oblique inguinal hernia.—An uncommon peculiarity in the conformation of the sac itself of an oblique inguinal hernia occurs in consequence of a narrowing of its walls at a point corresponding with the site of the external abdominal ring, or a little below that point in the scrotum between the testis and that aperture. When a hernia fills the sac, it may become strangulated by this constriction. The outline of the hernial tumour, as well as that of the sac, exactly resembles the shape of the ordinary hour-glass: hence the name given to it. It is always associated with the congenitally open state of the vaginal process of the peritonæum. The result of the imperfect closure of this sheath at that part where union of its walls normally takes place is to give rise to the formation of a ring or circular constriction within this process of the peritonæum at the point where the tunica vaginalis propria testis and tunica vaginalis propria funiculi meet together. Instead of the upper division of this canal being closed, and the two divisions, by this means, rendered distinct from each other, they communicate freely. The result is, that a hernia passes through the abdominal orifice of the funicular portion of the canal, traverses it, and then passes through the constriction into the cavity of the tunica vaginalis propria testis, which gland it touches. Instances of this

¹ *An Account of a particular kind of Rupture, &c., viz. that in which the Intestine or Omentum is found in the same cavity and in contact with the Testicle*, by P. Pott. Lond. 1765, 2nd edit. p. 5.

constricted condition of the sac of an oblique inguinal hernia are related by Pott,¹ Wrisberg, Le Cat, Scarpa,² Pelletan, Sir A. Cooper, and Mr. Lawrence.

Case.—A labourer, 20 years old, was brought into Guy's Hospital in September 1858, in a state of great prostration, and having a rupture in the left side of the scrotum. There had never been any tumour noticed until seventy-eight hours before admission. All observers were struck with the small size of the neck of the tumour, its pear-shaped form, thus closely resembling the outline of a hydrocele, and the seeming absence of the left testis. The external abdominal ring was distinctly recognisable, and I could pass my fingers through it, but I could not make out distinctly the spermatic cord. On palpation a very audible gurgling sound was produced in that division of the swelling between the internal ring and the upper part of the scrotum, the integuments of which were red, tense, and shining. The whole tumour was divisible into a superior division and an inferior. This last, which was the largest, remained unaltered by manipulation, was firm, and resisted pressure, although slightly elastic, and was very painful when compressed. The upper division was soft, and the swelling entirely disappeared when slight pressure was applied; but it was reproduced by the contraction of the abdominal muscles, or by pressure on the abdomen above the internal ring. All the symptoms of strangulated intestine being strongly marked, and considering that the liberation of the hernia was imperative, I administered chloroform; and finding, when the man was fully under its influence, that I was still unable to reduce the protrusion, I determined to operate at once. An incision of the integuments, four inches long, was made, the direction of which was parallel with the long axis of the tumour, and the centre corresponded with the site of the external abdominal ring. This aperture, although seen, was not sharply defined. I could now pass my finger upwards on the outside of the hernial sac to the internal ring, and trace its boundary. A very distinct constriction was now seen in the body of the tumour, producing the form of an ordinary hour-glass. This constriction corresponded with the ramus of the pubes over which it crossed. I opened the superior division of the hernial sac above this constriction, and exposed healthy intestine only. I next endeavoured to extricate the bowel from the inferior division of the sac; but I was unable to release it. A grooved director was carefully introduced into the inferior sac, and much blood-tinged serum escaped along the groove. Still, even when all the serum had run out, and traction was made on the bowel from above, it was inextricable! What chance then was there of reducing the bowel by the taxis? The constriction of the sac having been divided, the strangulated bowel was easily returned into the abdominal cavity without any enlargement of its abdominal orifice being required. The left testis was visible at the fundus of the sac—sufficient evidence that the hernia had descended into the vaginal process of the peritonæum. This man recovered.

Other cases of this kind have occurred in my practice. They are not, I suspect, quite so uncommon as at first sight we might be led to assume. Out of forty cases of oblique inguinal hernia, which Mr. Kingdon selected for me, in order to illustrate quite a different subject, I find that he observed the characteristic hour-glass constriction of the scrotal tumour in four men in whom the hernia was developed at the respective ages of 17, 29, and 30 years, and one in boyhood.

But what explanation can be given of the constriction of the bowel by the sac at such an unusual part? Let us seek for it by an examination of preparations and a reference to the physiological changes taking place in the vaginal process of the peritonæum before, or soon after, birth. Before doing this, let us distinctly isolate and exclude from the class of cases about which we are writing all those in which the impediment to the reduction of the hernia, or the cause of constriction of the bowel, depends upon the development of adventitious bands crossing the cavity of the sac without any definite or specific arrangement. Hernial sacs, showing such peculiarities as last mentioned, are preserved in the London museums; but they are quite foreign to our immediate purpose, and belong to a perfectly distinct category as regards their development and relations to the sac and its contents.

In the cases we are now describing the hernial protrusion and testis are in contact, otherwise the case would not belong to this class.

In the Museum of the Royal College of Surgeons there is a Hunterian preparation, No. 1343, thus described in the catalogue: 'The sac of a large congenital hernia. The exterior of the sac is uneven and sacculated, though the unequal yielding of different parts of its walls: the testicle is situated at the lowest part.' This account is not sufficiently explicit or descriptive of the structure of the hernial sac and its relations to the testis. A careful examination of the interior of the sac shows a large superior division and a small inferior. In the latter the testis may be recognised; but between the divisions an imperfect septum, or perforated diaphragm, existed before the vertical section of the entire sac was made, and by means of this foramen a communication was established between them. The sharp, well-defined, free edges of this septum are seen stretching from the sac-wall to the testis, as well as its strong attachment to the sac itself. Now assume the cut edges of this sac to be joined

¹ *Chir. Works*, edit. 8vo, 1808, vol. ii. pp. 118, 184, case xiv.

² *A Treatise on Hernia*; translated by Wishart, 8vo. 1814, p. 138, pl. v. fig. 2.

together, and the superior and inferior sacculi would be complete, although any foreign body might be passed from the one into the other. A hernia, for example, filling the upper sacculus, might pass from it through the aperture in the diaphragm into the lower, and then become constricted by the margins of this annular contraction.

But a preparation in the Museum at Guy's Hospital, No. 2368, at once affords a satisfactory clue to the solution of these somewhat remarkable cases. It is the vaginal process of the peritonæum taken from a child. It shows a portion of the parietal peritonæum of the abdomen with the whole process extending downwards from it. This process has been opened along the whole extent of its anterior surface. At the superior extremity the canal communicated with the abdomen, and at the inferior extremity the testis may be seen; and between these two points, about midway, the cavity is contracted. When this tube was uncut, there must have been an opening or narrow passage near its centre, through which a protrusion, escaping by the abdominal orifice, and traversing the funicular portion of the vaginal process, must have passed to reach the testis. A constriction resembling this formed the impediment to the reduction of the hernia in the cases above described.

Sir Charles Bell describes a hernial sac of this kind which came under his observation in connection with an obscure case of hernia, which he has recorded in the 'London Medical Gazette' of 1828.¹ 'There was another remarkable circumstance observed, which related to the sac lodged in the scrotum. At the lowest part there was a hole of communication between that sac and the cavity which is between the coats of the testicle. This orifice was so large that the finger could be passed through it; and its margins were so dense as to resist dilatation.' In the explanation of the woodcut, he writes: 'A bougie has been passed from the hernial sac into the cavity formed by the tunics of the testicle, through an opening which forms a communication between them.'

A careful examination of the second figure of the 2nd plate of Key's edition of Sir Astley Cooper's work on Hernia will satisfy any one that it delineates a case of the kind we are describing. It was a 'congenital hernia firmly constricted by an annular contraction of the sac itself,' although described as a 'band of membrane adhering to the sides of the tunica vaginalis, through an aperture in which the intestine has protruded and become strangulated.' The hernia is seen both above and below this aperture: the portion below 'discoloured by the effects of strangulation' produced by its margins; the portion above, 'below the internal ring and above the strangulating band, free from pressure and retaining its natural appearance.' Now in this description we have but a repetition of the appearances I observed in the case under my own treatment, related on the previous page. In chap. xvi. on *Congenital Hernia*, Sir Astley Cooper states that in this variety 'the stricture is much oftener found to be within the sac than in the ordinary kinds of hernia;' and he relates a case, upon the authority of Mr. Hodgson, of Lewes, in which the intestine 'was found strangulated within an aperture of the tunica vaginalis. The intestine appeared to have suffered more from this stricture than from the ring.'

Lastly, Mr. Lawrence,² when describing cases of this kind, records one in which, 'about half-way between the testis and groin, the hernial sac was so contracted that a probe only would pass into the stricture.' In this case, too, the abdominal orifice of the sac 'would not admit the smallest portion of the tip of the finger,' and it also formed an impediment to the reduction of the hernia; in this respect differing from my case.

By these quotations, to which numerous instances might be added, especially those recorded by Mr. Pott, with dissections, case 14,³ it is capable of demonstration that this class of cases must be confined to those forms of inguinal hernia dependent upon congenital defect or persistence of the vaginal process of the peritonæum throughout life.

But a glance at a plate in Camper's work⁴ will more easily explain the nature of these cases. Fig. 2 shows the cavity of the right vaginal process of the peritonæum opened vertically from the abdomen to its inferior termination; at which point is seen the testis. Fig. 3 shows the left side, in which, just above the testis, the entire canal is divided into two portions by the internal surfaces of the serous membrane united together. Should it, however, happen that this septum is not complete, a mere contraction takes place, and a ring is thus formed, keeping up a communication between the persistent funicular portion of the vaginal process, which is above, and the cavity of the imperfect tunica vaginalis testis below. By the constant pressure around a hernia, the tissues composing this annular contraction of the hernial sac become more and more dense, until it forms a firm, fibrous callous ring at the situation where the tunica vaginalis ordinarily terminates just above the testis; its variable distance from that gland depending, in different cases, upon the larger

¹ Vol. i. p. 484; also a woodcut.

⁴ *Icones Herniarum*, tab. x. 1801.

or smaller size of the protrusion, and the consequent distension of the tunica vaginalis testis.

The differential diagnosis between these cases, of hernia into the vaginal process of the peritonæum, and the ordinary form of inguino-scrotal hernia, is formed by the manner of their development, the age at which they first appear, and their configuration. Whilst the common form is developed slowly, these appear suddenly, and often pass at once into the scrotum without resting in the inguinal canal. They are noticed in the earliest infancy, throughout childhood, and during early adult life. Their form or outline is highly characteristic. The tumour projects in a remarkable manner from the external outlet of the inguinal canal; directly the rupture escapes from the embrace of the external abdominal ring, the form is more globular and rounded in comparison with the pyriform outline of the hernia of slow formation in adult life. The testis may or may not be felt, when it is easily detected, it is evident that the gland and rupture are in separate sacs, and *vice versa*.

In the hour-glass shaped variety the configuration alone is sufficient to attract notice and lead to its diagnosis.

When the hernia is reducible, the depth of the internal abdominal ring and the length of the inguinal canal are discoverable by tactile examination.

The importance of recognising these cases.—It is highly important to recognise the cases of hernia into the vaginal process of the peritonæum, in a practical point of view, especially in relation to their treatment. Much more severe constitutional symptoms usually accompany strangulation in these cases, and this condition of the hernia takes place more rapidly than when the hernial sac has been of slow formation. They require, therefore, the liberation of the bowel as soon as it is possible.

Considerable difficulty is experienced in reducing these protrusions by the taxis, in consequence of the depth of the orifice of the sac, the inability of the operator to fix it or command its movements, the contraction of its orifice, its unyielding textures, and the length of the neck of the sac, or that part of it lying between the two inguinal rings within the inguinal canal. In cases of the hour-glass contraction of the sac, the taxis is generally useless if the bowel has been strangulated but a few hours, and persistence in such attempts is extremely hazardous. Under any conditions, the surgeon must remember that two distinct and separate contractions exist, through which the rupture must have passed; one of these being situated in the body of the sac, the other being its true ventral orifice. Either of these contractions, or both of them, may offer insuperable impediments to the reduction of the hernia, unless their tissues be cut.

If we scrutinise any large number of cases of inguinal hernia admitted into the hospitals, a majority of those requiring the liberation of the bowel by a cutting operation are patients under 30 years of age. At St. George's Hospital, out of 28 males suffering with strangulated oblique hernia, 17 were under 30 years of age; 11 had passed that age.¹ At Guy's Hospital, of 57 cutting operations performed in order to liberate a strangulated inguinal hernia, 33 belonged to the class of which we are writing, 24 were of the old slowly forming variety. Next, in order to demonstrate with how much greater facility the old inguino-scrotal hernia is reduced by the taxis, than that descending into the vaginal process of the peritonæum, we may refer to 129 cases of oblique inguinal hernia, admitted also into Guy's Hospital.

Of these, 59 had traversed the canal of the vaginal process of the peritonæum, 70 belonged to the old inguino-scrotal variety. Or, tabulated thus:

Of inguino-scrotal, the sac of which formed slowly	94 cases	requiring a cutting operation	. 24 or 25·53 per cent.
		reduced by taxis	. 70 „ 74·46 „
Of ing.-scrotal descend- ing along the vaginal process of peritonæum	92 cases	requiring a cutting operation	. 33 or 35·86 per cent.
		reduced by taxis	. 59 „ 63·04 „

¹ *Medical Times and Gazette*, 1861, vol. i. p. 624.

Another subject of great importance relates to the application of the taxis. In some of those cases in which the hernia, when strangulated by the orifice of the sac, was supposed to have been returned into the abdomen in a mass, more careful examination after death showed that the inguinal portion of the sac was burst, and that the bowel had been pushed through the laceration, and was lying outside the peritonæum, between it and the internal abdominal fascia. This accident is more fully described at page 780. In these cases, also, the mouth of the sac is sometimes detached from its connections. When the patient is youthful, and the anæsthetic effects of chloroform are fully produced, great caution is, therefore, necessary in using the taxis, on account of the slight and delicate connections of the peritonæum to the neighbouring parts at this early age.

Difficulties also attend the operations on these cases, in consequence of the depth of the orifice of the sac, the variable position of the testis, and the varieties which may be encountered in the disposition of the hernial sac, all of which have been before described.

Infantile hernia.—The infantile hernia of Hey, and the encysted hernia of the tunica vaginalis of Astley Cooper, are synonymous terms for a variety of the oblique inguinal hernia, depending likewise upon an abnormal condition of the tunica vaginalis peritonæi. The state of that sheath which precedes the development of this kind of hernia depends upon the ventral orifice being closed, but the canal persisting from that point to the testis. The hernia slowly pushes before it the parietal peritonæum of the abdomen into this sheath, and when the parts are dissected it is seen that 'the tunica vaginalis is continued up to the abdominal ring, and encloses the hernial sac,' as Mr Hey describes. In this manner 'the protruded parts, together with the sac, are contained in the tunica vaginalis testis' (Lawrence, 'A Treatise on Ruptures,' p. 576).

The name given by Hey to this variety of hernia leads the reader to infer that it is always developed in infancy. This, however, is not the fact. Hey's case was an infant, fifteen months old. Forster's case, related by Cooper, was thirty-one years old at the time of the operation. The duration of the rupture is not specially stated, but the description induces us to believe that it had not existed long. In Lucas's case the rupture was developed at about seventeen years of age. The man in Forster's second case had been ruptured all his life. Mr. Holmes reports a case in which the rupture was developed at about twelve years of age; and I operated upon a man in Guy's Hospital, forty-two years old, who was not ruptured until he had completed his thirty-fifth year.

Cases of this kind are very rare. Their precise nature is usually only detected during the time of the operation, when the surgeon finds that on cutting into the tumour, a serous cavity is opened, which contains the hernial sac, invested externally by a serous membrane. Within this, the true hernial sac, the rupture is found. The operator may also be a little puzzled by finding the tumour so remarkably movable, after he has incised the first serous sac. The whole tumour, with the testis attached to its walls, falls out, and seems to be only suspended by its attachment to the margins of the external abdominal ring.

Inguino-scrotal hernia of slow formation.—That variety of oblique inguino-scrotal hernia which occurs in middle and late adult life, and forms for itself its own sac by pushing the parietal peritonæum before it, causes at first a slight swelling at the internal abdominal ring, slowly traverses the inguinal canal, and at last occupies more or less of the scrotum. To the 'pointing' of the hernia at the internal inguinal ring, as M. Malgaigne aptly terms it, the attention of the surgeon is sometimes drawn. Upon inspection, a slight elevation of the integuments over the internal inguinal ring is observable, which becomes more prominent when the patient contracts the abdominal muscles or coughs, especially if standing erect. In this posture, and under similar influences, if the finger be placed over the ring, the hernia is projected against it, and the sensation thus induced is termed the impulse of the rupture.

At this period a truss should be constantly worn. If made to fit comfortably, it will prevent the further escape of the viscera; and by counteracting their propelling force against the parietal peritonæum, the development of the hernial sac is arrested.

As the hernia descends further from the internal inguinal ring, it produces a swelling in the inguinal canal. The long axis of the tumour is parallel with Poupart's ligament, and therefore follows the oblique direction of that firm, fibrous structure, from above, downwards and inwards. This bubonocoele, as the tumour is usually called, is covered by the integuments of the groin and the aponeurosis of the external abdominal oblique muscle. Along its superior border it is overlapped by the free edge of the internal oblique and transversalis muscles; along its inferior by the cremaster muscle. It lies upon the internal abdominal fascia as it emerges at the internal inguinal ring, afterwards upon the conjoined tendons of the internal oblique and transversalis muscles, just before it reaches the external inguinal ring. Under these dispositions of the fleshy and tendinous fibres of the abdominal muscles, the hernial sac with its contents is in a very especial manner under the influence of their contractions; more especially in the region of its mouth and neck: hence a frequent impediment to the reduction of a hernia. The spermatic cord usually lies behind the tumour at the internal inguinal ring, and is attached to the posterior surface of the sac as it traverses the inguinal canal.

As the development of the sac advances, it is pushed through the external inguinal ring, over the os pubis, and into the scrotum. As the hernia points at the external inguinal ring, it forms a somewhat globular swelling; but as its bulk increases, in its progress towards the fundus of the scrotum, the shape of the tumour is generally pyriform, when the scrotum is distended with the hernia. In the body of the tumour contractions or depressions, generally following an oblique or transverse direction, are occasionally observable. Such appearances are due to the more or less yielding tissues of the scrotum.

The testis is usually below the tumour, sometimes behind it. The elementary structures of the spermatic cord may be traced along its posterior or outer boundary, generally close together, side by side, but sometimes, though very rarely, separated from each other.

When the hernia is reduced, the forefinger may be passed with facility into the abdominal cavity through the external inguinal ring, the inguinal canal, much shortened, and the internal inguinal ring. This is practicable on account of the approximation of those rings taking place from the pressure of the hernia, and the relaxation of the surrounding structures. The mouth of the sac and the inguinal apertures are indeed sometimes so stretched that the finger may be freely passed to the abdominal surface of the symphysis pubis, and the pulsation of the epigastric artery, or of the external iliac, may be felt in the usual situations of those vessels.

Diagnostication.—Every inguinal hernia escapes from the abdominal cavity above Poupart's ligament. If, therefore, the tumour formed by an inguinal protrusion be examined whilst in the inguinal canal, Poupart's ligament is traceable along its inferior border, and the opening where the tumour seems to make its escape from the abdomen is above the same fibrous band. It may be always distinguished, then, from crural hernia; for that kind generally escapes through the crural ring, which is situated behind and below Poupart's ligament, and that ligament may be always traced along the superior border of the tumour. Figs. 163, 167 should be compared.

Again, an inguinal hernia reaches the scrotum through the external inguinal ring, the outer pillar of which is formed by the pubic attachment of Poupart's ligament to the spinous process of the pubes. Now place the tip of the finger upon the last-mentioned process of bone, and if the neck of the tumour lies to its inner side, or between the finger and the symphysis pubes, the tumour must be formed by a protrusion which has passed through the external inguinal ring; a fact sufficiently demonstrative of an inguinal hernia. Should the tumour be to the outer side of the finger, the probability is that the hernia has passed through the crural ring.

A Tabular Arrangement of the Characteristics of the three varieties of Oblique Inguinal Hernia in Males.

A. INTO THE VAGINAL PROCESS OF THE PERITONÆUM. (<i>Hernia congenita Halleri.</i>)	B. INTO THE FUNICULAR PORTION OF THE VAGINAL PROCESS OF THE PERITONÆUM	C. INGUINO-SCROTAL; INTO THE TISSUES OF THE SCROTUM
<p>1. Is developed most commonly in infancy; occasionally in youth; rarely in adult life.</p> <p>2. Is suddenly produced.</p> <p>3. At once descends along the inguinal canal into the scrotum.</p> <p>4. May rest in the inguinal canal when the testis is not in the scrotum.</p> <p>5. Envelops the testis, and lies in contact with that organ.</p> <p>6. The orifice of the hernial sac is contracted, and corresponds with the site of the internal abdominal ring.</p> <p>7. Neck of the sac long and tubular; it lies in the inguinal canal, between the rings, which are not approximated, even in the adult.</p> <p>8. Hernial sac a direct congenital prolongation of the peritonæum; tubular when not distended with a hernia. It reaches the testis in the scrotum, and envelops it. Thus there is a congenital serous canal to receive the hernia.</p>	<p>1. Is developed frequently in infancy; often in youth and in adult life.</p> <p>2. The same.</p> <p>3. The same.</p> <p>4. May rest in the inguinal canal when the testis is in the scrotum.</p> <p>5. The testis, at the fundus of the scrotum, occupies its own serous sac, which separates it from the funia. It usually produces a very distinct prominence at this part.</p> <p>6. The same.</p> <p>7. The same.</p> <p>8. Hernial sac, a direct congenital prolongation of the peritonæum; tubular when not distended with a hernia. It does not extend into the scrotum so low as the testis. A congenital serous canal exists to receive the hernia.</p>	<p>1. Occurs in adults, I believe, exclusively.</p> <p>2. Is slowly produced.</p> <p>3. By slow degrees traverses the inguinal canal and scrotum.</p> <p>4. May remain in the inguinal canal for an indefinite period, the testis being in the scrotum.</p> <p>5. Is separate from the testis, which is at the fundus of the scrotum, usually.</p> <p>6. Orifice of the sac large and near the external abdominal ring.</p> <p>7. Neck of sac short, dilated; inguinal canal shortened; the rings being approximated.</p> <p>8. Hernial sac a new formation, and slowly developed by the pressure of the abdominal viscera against the parietal abdominal peritonæum, which by extension before the hernia is thus formed into a sac for it. Here the hernia forms its own sac by pushing the peritonæum before it. The tubular character of the sac is wanting.</p>

Differential diagnostication.—The surgeon is often required to distinguish between inguino-scrotal hernia and some other tumours developed in the inguinal region and scrotum.

These are—1st, the different kinds of hydrocele; 2nd, the encysted spermatocele connected with the epididymis; 3rd, varicocele of the spermatic veins; 4th, inflammation of an old hernial sac, and the results of such inflammation; 5th, inflammatory affections and other diseases of the testis, the cord, and their coverings; 6th, hæmatocele; 7th, malpositions of the testis; 8th, inflammatory and other diseases of the inguinal lymphatic glands; 9th, growths of fat in the connective tissue of the inguinal canal and upon the spermatic cord; 10th, diseases of the integuments of the scrotum, especially growths, as elephantiasis.

The nature of these diseases being described in other parts of this work, the observations we have to make in relation to the differential diagnosis between them and inguino-scrotal ruptures may be condensed into a tabular form. This plan was suggested by the perusal of a chapter written by M. Vidal (de Cassis), entitled 'Chronic Tumours of the Scrotum considered in a Diagnostic Point of View.'¹

To one variety of hydrocele it is perhaps necessary to make a special allusion. In rare instances serum collects in the vaginal process of the peritonæum, when its ventral orifice is patent, and the accumulated fluid may be pressed out of the scrotum into the peritoneal cavity through that aperture. This condition usually occurs in infants, but we have seen it in adults, complicated even with a hernia. The differential diagnosis is stated in the table.

The chronic tumours of the scrotum may be arranged in two divisions :

- I. The reducible. (See table below.)
- II. The irreducible. (See table on next page.)

Characteristics of the Reducible Tumours compared with Hernia.

	Their entrance or return into the abdomen		Their passage from the abdomen
	Characters in common	Special characters : when without complications	Special characters
1. INGUINAL HERNIA.	All return into the abdomen most easily when the patient lies down on the back and when the abdominal muscles are relaxed.	1. <i>Hernia</i> enters most readily. When once commenced, passes in quickly and suddenly. Entrance complete. Opaque and thick neck of tumour. Testis may or may not be perceptible until reduced. No vibration.	1. Is developed from above, descends when the patient rises or exerts the abdominal muscles, and more quickly than others. The finger pressed over the ring prevents its descent.
2. HYDROCELE OF VAGINAL PROCESS OF PERITONÆUM.		2. <i>Hydrocele</i> of vaginal process of peritonæum enters slowly, and never suddenly. Entrance complete. Translucent and small neck of tumour. Testis imperceptible until the fluid has entered the abdomen. Vibration.	2. Seems to be developed from below upwards. The serum sometimes remains in spite of the horizontal position.
3. HYDROCELE OF FUNICULAR DIVISION OF VAGINAL PROCESS OF PERITONÆUM.		3. <i>Hydrocele</i> of funicular division of vaginal process of peritonæum enters like No. 2. Entrance complete. Translucent. Neck of tumour may pass into inguinal canal. Testis perceptible at fundus of tumour. Vibration.	3. Similar to No. 2.
4. VARICOCELE		4. <i>Varicocele</i> enters very slowly. Entrance not complete, the bulk of tumour only diminished. No vibration.	4. The tumour increases like hernia when the patient rises; but it increases also if pressure be made over the course of the spermatic veins in the inguinal canal, or if the blood be retarded in its passage along them in any way.

¹ *Traité de Path. externe*, édit. 1841, vol. v. p. 715.

Characteristics of the Irreducible Tumours compared with Hernia.

Disease	Weight	Transparency	Fluctuation and vibration	It is full of testis or not	Figure and development	Size	Consistence	Pain
HERNIA	Lighter than either the fluid or solid tumours.	Very rarely so; generally opaque.	Only when fluid co-exists with the hernia.	Position variable, but the testis usually discoverable.	Pyramidal, but with thick neck. Occasionally globular or ovoid. Outline irregular. Begins at neck of scrotum and descends.	Variable; at times very large.	Soft and yielding, except it be omental.	Painless, unless eased.
FLUID TUMOURS	Hematocoele rather heavier than hydrocele.	Hydrocele particularly so. In rare cases opaque. Hematocoele opaque.	Distinct; vibration very characteristic. Heavier as in hydrocele.	Perceptible in spermatocele, not in hydrocele of tunica vaginalis, properly testis, usually.	Pyramidal, but with very thin neck. Outline very regular (globular as hydrocele of spermatocele). Oblong in spermatocele, and nearly transverse to vertical axis of scrotum. Begins near fundus of scrotum and ascends.	Rarely very large.	Yielding and elastic. Exceedingly incompressible as hydrocele of cord.	Painless, unless testis be squeezed, usually.
SOLID TUMOURS	Generally heavier than fluid.	Opaque.	Absent.	Often involved and imperceptible though its site may be discoverable by pressure.	Outline of testis often preserved. Sometimes surface irregular.	Large; steadily increasing.	Resisting, firm and rarely hard.	Painful, but variable in degree.
MIXED TUMOURS	Heavy.	Sometimes in parts of them.	In some parts, not in others.	Involved.	Irregular outline.	Large, at times rapidly increasing.	Resisting in parts, soft in others.	Variable.

In the first division there are :

1. Inguinal hernia.
2. Hydrocele of the vaginal process of the peritonæum.
3. Hydrocele of the funicular portion of the same process.
4. Varicocele of the spermatic veins.

The tumours in the second division are composed very often of fluids only, sometimes almost exclusively of solids, but occasionally of both solids and fluids in variable proportions.

Those composed of fluids are—1, hydrocele of the tunica vaginalis propria testis ; 2, hæmatocele in the same sac when first developed ; 3, encysted spermatocele connected with the epididymis ; 4, hydrocele of the spermatic cord.

Those formed by solids, or of solids and fluids, are —1, the diseases of the testis, *a*, of inflammatory origin, *b*, specific new growths ; 2, hæmatocele of some standing in which changes have taken place ; 3, diseases of the spermatic cord ; 4, growths of fat extending from the inguinal canal into the scrotum or in its tissues ; 5, diseases of the tissues of the scrotum.

Between the local signs of an inflamed scrotal hernial sac, especially if its orifice be plugged by omentum, and an inflamed hernia, there is a close resemblance. But from the history of the case, and the absence of those constitutional symptoms which accompany an inflamed hernia, a correct diagnostication may be formed.

The inflammatory conditions of the testis, the cord, its coverings, and the tissues of the scrotum, do not resemble hernial tumours either in their local or constitutional manifestations. It is more probable that a hernial protrusion might be considered to be some affection of those organs, than that they should be mistaken for a hernia. The history of the case usually removes all doubt as to its nature.

Treatment.—The palliative treatment of reducible oblique inguinal hernia consists in maintaining perfect and unintermitting retention of the hernia ; for if this be done carefully and with method, a permanent cure may be effected, especially in children. The cases of hernia into the vaginal process, if carefully treated immediately after the first appearance of the rupture, and before the walls of that canal have been stretched for any length of time, are generally cured by the employment of a well-adjusted truss. But in the use of this instrument before puberty, great attention must be given to the site of the testis ; for the pad of the truss might press injuriously upon that organ. The spring of the truss must not be too powerful ; for if the pressure of the pad upon the walls of the abdomen is very strong, their tissues are absorbed where the pad presses, and they become, in consequence, seriously weakened. The pad should prevent the escape of the hernia by its accurate adjustment, rather than by the force with which it presses against those apertures through which the hernia passes. On this account, each individual requires to have a truss adapted to the configuration of the body. The pad should be applied over the internal inguinal ring, pressing gently upon the inguinal canal to afford support to the tissues of that part, and not upon the external inguinal ring and pubes, as we have often seen it applied. The patient should be enjoined to wear the truss uninterruptedly, except only when lying in bed ; to adjust it carefully before leaving bed in the morning, and on no account to permit the hernia to remain for a moment in the sac.

When the hernia has acquired large dimensions, or has become irreducible, a particular form of appliance, termed the bag-truss, becomes indispensable.

The radical cure of reducible inguinal hernia.—The commonly unsuccessful issue of the operations performed on the principle of invagination, as advocated by Gerdy, Wutzer, and others, induced Mr. Wood to search for the cause of failure. This he attributes to the want of union between the invaginated tissues and those lying behind them. The theory of Wutzer's operation is to induce adhesion between the fundus of the hernial sac and the entire circumference of its orifice, as well as entire obliteration of the other parts of the sac by adhesive inflammation. Unfortunately, however, the results of practice do not uphold the theory.¹

¹ See page 700 for the general principles which should guide the surgeon as to these operations.

Mr. Wood¹ has contrived an operation by which he believes the chances of failure above mentioned are prevented. The operator requires a special needle, scalpel, compress made of wood, glass, or porcelain, and some strong hempen thread. The contraction of the abdominal muscles should be completely controlled by the influence of chloroform.

After an incision has been made through the skin of the scrotum, the forefinger of the operator is pushed behind the hernial sac as far as possible into the inguinal canal, and in front of the spermatic cord, at the same time invaginating the tissues. The needle is next carried by the side of the finger and passed through the conjoined tendons of the internal oblique and transversalis muscles, the inner pillar of the external inguinal ring, and the integuments. Great care is required to avoid including the spermatic cord. A thread is next passed through the eye of the needle, and the latter is withdrawn, leaving one end of the thread in the puncture. The needle, still threaded, is next passed through the aponeurosis of the external abdominal oblique muscle near to Poupart's ligament, and opposite to the internal inguinal ring, and its point brought out through the opening in the integuments first made by it. A loop of thread is left behind, and the needle, with the thread still in it, is again passed through that portion of the conjoined tendons which lies over the rectus muscle, close to the pubic spine and the inner pillar of the ring. Its point is now brought through the first puncture for the third time, and the needle altogether withdrawn from the thread.

Thus a loop and two ends of thread pass through one opening in the skin. Two portions of thread are thus placed across the hernial canal, invaginated fascia and sac, closely embracing, but not including, the spermatic cord, and connecting the posterior or deep wall with the anterior and superficial, perforating the aponeurosis of the external abdominal oblique muscle in three places; but escaping by the same aperture in the skin' (Wood). The compress is next applied over the canal obliquely, and the two ends of the thread passed under the loop and tied in such a manner as to give equable adjustment to the pressure.

The after-treatment of the case is the same as that adopted in similar operations.

Mr. Wood described several modifications of this operation in which wire was used with good results.

The taxis.—When a surgeon has a case of irreducible inguinal hernia to treat, his attention should be particularly devoted to a very careful examination of the tumour, in order to diagnosticate the variety under observation. He should ascertain with accuracy the anatomical relations of the tumour to the surrounding parts; the position of the testis, especially; the length of time the patient has been ruptured; the mode of development of the hernia, whether suddenly or slowly; the treatment pursued to prevent the protrusion from taking place; and the history of the present state of the rupture.

Having determined the variety, if the state of the tumour permit, he may employ gentle pressure in order to reduce the protrusion, remembering the direction or course it has taken, and the circumstances which probably cause the impediment to its reduction. The abdominal muscles must be relaxed as much as possible whilst the patient lies on the back.

It is only necessary to describe, in this place, the manipulative proceedings, as the constitutional measures employed to render them more effective have been detailed at pp. 775-6. A very much larger proportion of the cases of inguinal hernia are now reduced by taxis than formerly. This is due to the use of chloroform, the effects of which in producing total annihilation of the contractile function of muscular tissue are so important. Small inguino-scrotal protrusions are not reduced with the same facility as large ones. When such a protrusion occurs in a young person, and has been only recently developed, after a fair trial of the taxis, when the patient is fully under the influence of chloroform, and the efforts to reduce it have failed, any delay

¹ *On Rupture: Inguinal, Crural, and Umbilical, &c.*, by John Wood. 8vo. London, 1803.

in removing the impediment to the replacement of the hernia is reprehensible. To resort to any other measure which necessitates the occupation of time, is only to abandon the sufferer to additional risk of the loss of life.

If the protrusion be compound—that is to say, when it consists of a large mass of omentum and a very small knuckle of bowel—the reduction of the latter is effected with difficulty. The same thing occurs when the hernia is one of irreducible omentum of long standing, from old adhesions, and a small piece of bowel. Also, when the sac is distended and rendered very tense by a considerable effusion of serum. The efforts of the surgeon to reduce the bowel are thereby rendered abortive; for if the serum cannot be made to pass through the mouth of the sac into the abdomen, the hernia never will.

The operation.—The patient should lie on the back, with the pelvic region slightly elevated, unless some firm, resisting body, as a mattress, cushion, or table, be underneath. The anatomical points which the surgeon particularly wishes to reach or display in the cutting operation are, the external inguinal ring, the aponeurosis of the external abdominal oblique muscle, the internal inguinal ring, and the mouth of the hernial sac. The various structures which constitute the coverings of the hernial sac need not be displayed with rigorous anatomical precision. They differ exceedingly in density and development in different cases. The length of the incision should not be proportioned to the size of the hernia. Its length must be just sufficient to expose freely the anatomical points alluded to above, and no more. In ordinary cases; the point of the scalpel should be inserted through the integuments at about one to two inches above the assumed centre of the external inguinal ring, and carried downwards upon the anterior surface of the tumour, to terminate about two or three inches below the same mark. The margins of the external inguinal ring are next carefully exposed, and their relations to the tumour examined. They should not be cut unless it be imperatively required to do so. The deeper coverings of the hernial sac are next carefully incised, with or without the assistance of a grooved director, until that important structure is reached.

The operator, pressing his finger upon the sac, next insinuates it through the external inguinal ring, in order to ascertain if there be any structures which firmly encircle the neck and orifice of the sac outside. Should he discover any, a grooved director may be guided by the finger underneath them, and they may be cut. After slight pressure made upon the sac, its contents are sometimes returned into the abdomen at this stage of the operation. If their reduction be not practicable, the peritoneal sac must next be opened. It must be done after the manner described at p. 783, and with great care. Probably some serum will escape when the sac is cut, but this is not always the case. The opening in the sac requires to be sufficiently large to allow the operator to reach its orifice easily, and to examine its contents. The index-finger is now passed along the anterior surface of the protrusion upwards towards the mouth of the sac, when an impediment to its further passage is encountered. The tissues which bound this narrow opening constitute the impediment to the reduction of the hernia. The operator next passes the hernia bistoury along a grooved director or upon his finger, through the mouth of the sac, and divides the structures in contact with the knife sufficiently to allow the ungual phalanx to be passed freely into the abdominal cavity. The direction of this incision should be parallel with the linea alba. A few small arteries are occasionally cut during the operation, which may be twisted immediately.

Oblique inguinal hernia in the female sex.—This variety occurs at very early periods of life. In fact, with the exception of umbilical hernia, it is the only kind developed before five years of age. Even until the age of puberty it is more common than any other variety. Its development in infancy is due to the patulous state of the vaginal process of the peritoneum, otherwise known by the name of the canal of Nuck. Doubtless such a condition of this process remains throughout early life, into which a hernia occasionally and suddenly descends. In the adult female this

hernia generally forms slowly after thirty years of age. But I have met with double inguinal hernia in a well-formed woman aged only twenty-four years, who had never been pregnant; she had worked hard, however.

Its anatomical relations are alike in both sexes, merely substituting the round ligament in the female for the spermatic cord of the male, and the labium pudendi for the scrotum.

It is commonly believed that inguinal hernia is much more rare in women than femoral. However, this belief seems to be unfounded. Mr. Kingdon's valuable tables show that in the years 1860 and 1861, 1,582 females at all ages, suffering with either one variety of hernia or the other, came under his observation. Of these 761 were afflicted with inguinal hernia, and 821 with femoral. Or, inguinal hernia was only thirty less than half the total number, whilst femoral was but thirty more than half. Mr. Kingdon told me that it is not uncommon to feel the ovary in the sac of an inguinal hernia of an infant.

The tumour formed by an inguino labial hernia rarely attains the size so often reached by inguino-scrotal. Still, we have seen one which descended more than half-way below the middle of the thigh, and the coverings of which had become so attenuated that the convolutions of the intestines were distinctly visible. When of moderate size, it is generally of a more globular figure, and it has a longer, more contracted, narrow, and cylindrical neck, than in the male sex.

In forming a correct diagnosis of this hernia in the female, the same anatomical points must be taken as guides which have been already described when that in the male sex was under consideration. The surgeon should, however, particularly remember that a hydrocele of the round ligament, or of the canal of Nuck, is occasionally developed, which might lead to an error in diagnosis.

The palliative measures described as being suitable in the treatment of cases of inguinal hernia in the male sex are applicable in these also; but if the hernia become strangulated, the surgeon must act with promptitude and decision. In the cases we have seen, under these circumstances, the symptoms have usually been rather severe at an early period of the attack; and in those upon which we have been required to operate, the impediment to the reduction of the bowel was at the orifice of the sac, and certainly insuperable without a cutting operation.

In the female sex, the operator must be guided by the same anatomical points in his attempt to reach the mouth of the hernial sac as in the male. And he should remember that, occasionally although very rarely, the bowel may be constricted by a contraction of the sac itself near the external inguinal ring, and not by its ventral orifice only.

Direct inguinal hernia.—The variety of inguinal hernia characterised by the term 'direct' occurs in both sexes. It belongs to that class in which the hernial sac is formed slowly, or is an accidental or acquired formation. The only exception to the slow mode of formation is in those rare cases when the structures immediately behind the external inguinal ring are lacerated by violence and a hernia protrudes. It is never the result of a congenital imperfection. This variety is sometimes styled the internal inguinal, from the fact that the mouth of the sac, where it is continuous with the parietal abdominal peritonæum, is placed to the inside of the internal epigastric artery. It is comparatively rare.

At its commencement it forms a prominence where it points behind the external inguinal ring, through which it passes into the upper part of the scrotum. The outline of the tumour which it forms is more globular than that produced by the oblique course of the variety before described. It seems to be produced by something which escapes at once or directly from the cavity of the abdomen. Hence, probably, its specific name. The mouth of the sac is close to the outer border of the pubic attachment of the rectus muscle, the posterior surface of which may be much more easily felt when the hernia is reduced than in the oblique variety. On the outer side of the orifice of the sac the pulsations of the internal epigastric artery may be felt.

The finger enters the abdominal cavity much more readily in direct inguinal hernia than in oblique. Upon ocular examination from a short distance it will be seen that a line passing through the vertical or long axis of the tumour lies parallel with the linea alba, and there does not appear to be any inclining or curving of the neck of the tumour outwards and towards the crest of the ilium, as is observed in one formed by oblique inguinal.

In its passage from the abdomen a direct hernia merely traverses that small portion of the inguinal canal which lies immediately behind the external inguinal ring, and those structures which form that part of the floor of that canal are either pushed before the hernia, or they are lacerated when the hernial sac escapes through the opening so formed. Those structures are the conjoined tendons of the internal oblique and transversalis muscles and the pubic portion of the internal abdominal fascia. The spermatic cord and round ligament are not attached to the hernial sac

FIG. 166.—Direct Inguinal Hernia.

until it has reached the external abdominal ring. When it has passed that point, they lie to its outer side, and are usually less identified with its tissues than in the oblique variety.

The diagnostication between this variety of inguinal hernia and oblique must be formed under the guidance of the facts before described.

The palliative treatment requires a particular kind of truss, which must be so constructed as to give support to the defective abdominal walls posterior to the external inguinal ring.

The method of exposing and opening the hernial sac to liberate a strangulated bowel does not require any special description here. Facts, however, worthy of note are, that after the division of those structures superficial to the external inguinal ring, the spermatic cord may appear to be unusually distinct, and that the deeply seated coverings of the hernial sac are often very attenuated. Considerable care is therefore required in the operation of incising them.

Inguinal hernie sometimes pass through abnormal apertures in the aponeurosis of the external abdominal oblique muscle.—It would be an oversight not to allude to the fact that an inguinal hernia sometimes passes through an opening or division of the fibres in the aponeurosis of the external abdominal oblique muscle close to the ring, and not through the true external inguinal ring, which is then traversed by the

spermatic cord alone. Such anatomical varieties are rare, and would only require some slight modification of the operation to meet their peculiarities.

Femoral hernia, also called *crural* or *merocele*, was not accurately distinguished from some forms of inguinal until the middle of the seventeenth century. Its designation in a measure indicates the region of the body where it forms a tumour, which, however, may be stated, with greater precision, to be the upper and inner part of the thigh. Its anatomical relations were not accurately defined for many years after it was known to pursue a different course to inguinal; and it is curious to follow the gradual development of our knowledge of those structures immediately interested in, or associated with, this variety of rupture.

The principal anatomical points which should be examined, from the outside of

FIG. 167. -Double Femoral Hernia, the outline of Poupart's ligament being remarkably distinct above the tumour formed by it.

the thigh as well as from within the abdomen, are the following. the ligament of Fallopius or of Poupart; Gimbernat's ligament; the crural canal or ring; the fascia transversalis and iliaca, or the internal abdominal fascia of the iliac fossa; the falciform process of the fascia lata and the saphenous opening; and, when a hernial sac exists, the fascia propria of Sir Astley Cooper.¹

Relations of the mouth of the hernial sac to the internal epigastric artery and vein. The orifice of the peritoneal sac holds important relations to the internal epigastric vessels. Some pathologists have established three varieties of the ordinary kind of crural hernia on this basis. The first, in which the orifice of the sac is situated to the outer side of the epigastric, external crural hernia; the second, where it lies to the inside of the same vessels, the middle crural hernia, the most common; the third, in which it is placed to the inner side of the remains of the obliterated umbilical artery. The first and third varieties are very rare.

Here we may also state that the obturator artery is occasionally given off from

¹ The anatomy of these various parts must be assumed to be known by the reader. We may, however, allude here to the importance of noticing the structure last named, viz. the fascia propria, first described by Sir Astley Cooper from a dissection made in 1800, and which is still preserved in the Museum of Guy's Hospital (No. 2508). It is an envelope which is found on the outside of the peritoneal sac, usually separated from it by a layer of adipose tissue.

the internal epigastric or femoral, and that when the former vessel lies to the outside of the orifice of the hernial sac, the obturator artery may cross closely over its neck, and dip down by its inner side to enter the obturator foramen.

A very interesting case, with a well-drawn illustration, is recorded by Mr. Spence in the 'Edinburgh Medical Journal,' July 1855. The pulsation of a large vessel was felt with the finger before its division.

Varieties in the course pursued by the sac of a crural hernia.—In a memoir published by Dr. Le Gendre, he describes four rare varieties of crural hernia.¹ They may indeed be regarded rather as curiosities, on account of their rarity.

1. The hernia, as soon as it traverses the crural ring, passes directly internal to and behind the femoral vessels, and rests on the pectineus muscle, the aponeurosis of which sometimes forms an envelope to it; this he calls the *pectineal crural hernia*, on account of its situation, or the hernia of Cloquet, in honour of the surgeon who was the first to describe it. Callisen, Vidal (de Cassis), M. Richet, Dr. Le Gendre, and Mr. J. Adams,² have recorded similar cases.

2. This variety, although placed internal to the femoral vessels, is, however, rather far from them; it passes through that resisting fibrous structure which bounds the crural canal and sheath internally; that is to say, the ligament of Gimbernat. Laugier, who was the first to notice it, calls it the *crural hernia through Gimbernat's ligament*, or the hernia of Laugier. Cruveilhier, Demeaux, Nuhn, and Le Gendre have also dissected cases of this kind.

3. This comprehends the variety of crural hernia which Hesselbach has so well described and figured.³ The hernia in this case traverses several openings in the fascia cribriformis, and then presents several distinct lobes, which give it a characteristic appearance; it is the *hernia with a diverticulum through the cribriform fascia*, or the hernia of Hesselbach. Le Gendre and Malgaigne have dissected examples of this variety of rupture, which the former believes to be not so very rare.

4. Lastly, a variety in which the hernia, after having escaped beneath Poupart's ligament and traversed the cribriform fascia, sends one or more prolongations through the superficial fascia. This variety may be termed the *crural hernia with a diverticulum through the superficial fascia*, or the hernia of Astley Cooper.⁴ Le Gendre describes a dissection of a case of this kind, and publishes a drawing of it in his work.

We may add a variety described by Mr. Partridge,⁵ in which the hernia was situated external to the femoral vessels.

Development of the sac of a crural hernia.—The peritoneal sac of a crural hernia is always a secondary or acquired formation. It is never the result of a congenital defect. An opportunity of observing the early stage of a crural hernial sac commonly occurs in post-mortem examinations. The point of the finger may be pressed into a fossa, or even a sacculus, of two or three inches in length, between the femoral vein and Gimbernat's ligament. An observer is enabled, in this way, to thrust the parietal peritonæum down upon the thigh at this spot for an inch or more below Poupart's ligament. And this opportunity is the most favourable for the study of the relations of the sac of a crural hernia. By degrees such a digital depression of the peritonæum at the crural ring becomes in a living person dilated into a sac by the repeated and continued pressure of the viscus which forms the hernia. The sac extends lower down upon the thigh beneath Poupart's ligament; but, instead of descending lower and lower towards the knee, it usually dilates in a direction towards the crest of the ilium, so that the long axis of the tumour lies parallel with

¹ *Mém. sur quelques variétés rares de la Hernie crurale; avec 6 planches.* 8vo. Paris, 1858.

Poupart's ligament and upon the fascia lata. When large, the tumour even overlies that ligament, and seems to occupy the region in front of the inguinal canal. But in every case of crural hernia the tumour is formed by a protrusion which has escaped from the abdominal cavity below and behind Poupart's ligament; therefore the surgeon is able to trace that structure running along its upper border.

Crural hernia rarely increases to the size of inguinal. But occasionally, after an operation for the liberation of a strangulated bowel, when the tissues around the crural aperture have been weakened by cutting them, and the sufferer has neglected to employ the support afforded by a truss, nearly the whole of the alimentary canal may protrude. In such cases the walls of the sac become so remarkably attenuated that the peristaltic movement of the intestinal convolutions is distinctly seen through them; so attenuated as even to excite astonishment that the vitality of the integuments should be maintained. A very rare variety, as regards figure, we once saw in a man. The tumour was of a cylindrical shape, and extended downwards and inwards over the thigh, reaching as low as the middle of that region. The great size of the tumour is not a feature of serious importance, for a very small sac, having a contracted orifice, more readily entangles the hernia and prevents its reduction.

Diagnosis; first, from other kinds of hernia. Those with which crural may be confounded are inguinal above Poupart's ligament, and obturator below the horizontal ramus of the pubes. It would seem to be impossible, however, to mistake a crural hernia for an inguinal, or *vice versa*, if the observer will but carefully trace the outline of Poupart's ligament. But he must remember that the fundus of the sac of a crural hernia sometimes takes a course upwards, and overlies that structure. Nevertheless, the course of Poupart's ligament can be always ascertained with more or less precision; whether an inguinal hernia overlies it from above—a very rare occurrence—or a crural from below, which is very common, the fingers of the examiner can still trace it from the ilium to the pubes—of course, in one case more distinctly than in another. If the whole of the tumour lies below the ligament, and its neck can be traced continuous with the crural aperture, its contents have escaped beneath Poupart's ligament, and it is a crural rupture; but if the contrary, it is an inguinal, especially too if the neck be traceable to the internal inguinal ring. Crural is distinguishable from inguino-labial hernia by placing the finger on the spine of the pubes, or upon the attachment of the tendon of the adductor longus into that point of bone; for even in very fat persons the pubic spine can be always felt. If the tumour be to its outer side, the protrusion has escaped below Poupart's ligament, in which case it is crural rupture; if, on the contrary, it has passed through the external inguinal ring, it must be an inguinal. The same point of bone will aid in distinguishing between a pudendal hernia and a crural.

A crural hernia is much more superficially seated than an obturator, and in

FIG. 168.—A piece of the Ileum three feet from the Cæcum removed from a patient, aged 57, who had been operated upon for Strangulated Femoral Hernia of seventy-three hours' duration.

The patient survived the operation forty hours, and the first symptoms of the attack 118 hours. She had been in bad health previously, was extremely emaciated, and sank from exhaustion. Large and hard masses of scybala were found in the ileum as shown in the part of the bowel cut open. The small piece of bowel which had been in the sac, and was but little diseased, is indicated by the dotted line. The contracted and opened bowel below this contained mucus only. The figure in the centre represents the sac. Through its mouth a piece of glass rod is inserted; and although the sac is very small, it was remarkable for the layer of fat, *b*, between the peritoneum, *c*, which is not cut, and the fascia propria, *a*. (Museum Guy's Hospital, No. 477.)

consequence the tumour which the latter produces is neither so prominent nor so well defined as the former. The latter escapes from the pelvis behind the horizontal ramus of the pubes, and therefore Gimbernat's ligament and the crural aperture can be felt. The elevation of the integuments produced by an obturator-hernia is certainly in the locality of the crural aperture; but the depth of the tumour is its striking feature, and the facility with which the crural aperture can be felt is pathognomonic of the relations of the protrusion.

Crural hernia requires to be distinguished from other diseases which occur in the same region.

1. From *psoas abscess*.—The history of the case, the locality of the swelling, and

FIG. 169.—Demonstrates the appearances produced by a small Inguinal Hernia just pointing at the External Inguinal Ring, and a medium-sized Femoral Hernia, both on the same side, and the outline of Poupart's Ligament between those tumours. On the left side of the scrotum a tumour is produced by hydrocele of the tunica vaginalis testis. (From nature, and copied from a drawing in Guy's Hospital Museum.)

the results of a palpable examination of the tumour, are quite different from hernia. Psoas abscess is generally preceded by pain in the back, constitutional disturbance, and inability to extend the hip-joint completely without pain. These symptoms do not accompany a crural hernia. Psoas abscess does not burrow down below Poupart's ligament at the crural ring, but to the outer side of the sheath of the femoral vessels. But an infallible test that the tumour is formed by a circumscribed collection of fluid is obtained by placing the patient flat on the back, and then gently applying the right hand above Poupart's ligament and the left below it, or *vice versâ*. When pressure is made upon the swelling with one hand only, the other is elevated; and when the action is reversed, the opposite effect takes place. With this result on manipulation of the swelling, there can be no doubt of the nature of the disease.

2. *Enlargement of the lymphatic glands*.—The correct history of the development of the swelling will aid in forming the diagnosis, especially its permanence and progressive increase. If there be a suspicion that the tumour is of glandular origin, it is as well to institute a careful examination of those somewhat secluded regions in which certain specific ulcerations unfortunately occur, giving rise to angioleucitis.

3. *Dilated and varicose veins.*—We have seen a dilated vein and a tumour formed of varicose veins occupying the site of a femoral hernia; but the diagnosis was easily made by placing the patient in the recumbent posture, when the swelling disappeared. Digital pressure being made at the crural ring or upon the vein, the swelling was at once reproduced.

4. *Cysts in the superficial fascia.* Cysts are sometimes, although very rarely, developed in the region of the crural ring, in some cases associated with hernia, but sometimes without. The permanency of the swelling, its persistent and invariable size, the fluctuation discoverable on pressure, and the history of the case, are aids to correct diagnosis. When a cyst is present, and there are any symptoms suggestive of strangulated bowel, the propriety of accurately ascertaining the contents of the tumour by an exploration of its interior cannot be disputed.

Palliative treatment.—The treatment of crural hernia by the use of trusses is most important. The prevention of the dilatation of the sac is the primary point to which attention should be directed; and this may be accomplished by giving support in the region of the crural ring, especially if it be efficiently maintained.

We gladly avail ourselves of the large experience of Mr. Kingdon in offering a few observations regarding the use of trusses in this variety of hernia. In a truss to prevent the escape of a crural hernia, the spring should fall somewhat suddenly from the point where it passes around the hip, and lie along Poupart's ligament. The pad should be rather small and convex. The cross-strap should fasten high up on the shoulder of the spring, in order to keep the pad well down in the thigh. The thigh-strap should start from near the pad, and return, after encircling the thigh, to the pad itself. When Poupart's ligament, or rather the whole crural arch, is lax, and moves backwards and forwards with the varying size of the abdomen, the pad should press upon that ligament; for then the crural aperture is made smaller, and the rupture more efficiently maintained. For that purpose a larger and flatter pad is wanted. But when the crural arch is strong and steady, the smaller pad is both more effective, and, by reason of its smallness, more convenient and less incommodious. Also, it is less liable to displacement by the movements of the hip-joint.

When the rupture is large, or where it comes down under the fascia lata, it is necessary to use a thigh-belt, with a triangular pad projecting on the inner surface, and forming a soft continuation of the pad, to fill the triangular space where the cribriform fascia occupies the saphenous opening of the fascia lata.

Sometimes after an operation, in which Gimbernat's ligament has been freely divided, a cross tongue in addition, to buckle to the free end of the truss, is needed.

Irreducible crural rupture of course requires a hollow pad, whether epiplocele purely, or enterocoele.

Attempts have been made to effect a radical cure of crural rupture by a cutting operation. The patients recovered from its effects, but we have no data by which to arrive at any conclusion as regards the advantages obtained.

Crural hernia very rarely occurs before puberty. I have seen one in a girl ten years old.

Crural hernia is much more common in the female sex than in the male. But the general belief, that it is much more common in women than inguinal, does not appear to be founded on facts. The following table demonstrates the proportions in which they occur. The comparative numerical equality is explained by the circumstance, that before puberty inguinal hernia is common, whilst crural is extremely rare. In 193 girls before 15 years of age, Mr. Kingdon met with 184 cases of inguinal rupture, and only 9 of crural. Even to the age of 20 years, the cases of inguinal hernia are much more common than femoral, as the subjoined table shows. In a total of 1,442 ruptured females, at all ages from birth upwards, the majority of the cases of crural hernia over inguinal was only 54.

After twenty years of age, crural hernia is much more commonly developed than inguinal.

Decades	Inguinal	Femoral
Birth to 10 years ¹	146	1
11 to 20 "	103	37
21 to 30 "	153	180
31 to 40 "	164	252
41 to 50 "	76	158
51 to 60 "	33	84
61 and upwards	19	36
Total	694	+ 748 = 1,442 cases. ¹
Total cases of femoral		748
Deduct cases between 20 and 40 years		432
At all other ages		316
After 40 years of age		278

This table demonstrates a fact for which the pathologist will be scarcely prepared, viz. that the largest number of cases of crural hernia is developed during those years usually termed the prime of life, i.e. in women between twenty years old and forty.

But it must be observed that this happens to be that period of life when parturition is most frequent, and when consequently the peritonæum and the tissues of the abdominal walls become much stretched by the development of the gravid uterus. Their power to resist the weight of the abdominal viscera becomes diminished; hence a cause of their protrusion.

To ascertain whether there was any relation between the development of hernia and parturition, Mr. Kingdon made the following table of 680 ruptured females, and found the proportion of mothers to be as follows: ²

	Inguinal	Femoral
Infants and girls under 16 years of age	87	3
Single women	50	61
Mothers	178	262
Married women who had not borne children	19	20
Total	334	+ 346 = 680

And next, with a view to ascertain the influence of repeated pregnancies upon the development of hernia, he examined 442 women who had been mothers before discovering the hernia. Of these, 180 women were afflicted with inguinal, 262 with femoral; which gives a majority of 82 in favour of femoral.

The influence of the first pregnancy is very remarkable. 442 women had been mothers before discovering the hernia:

	Inguinal	Femoral
67 had borne one child	27	40
51 " two children	26	25
53 " three "	22	31
55 " four "	23	32
40 " five "	15	25
25 " six "	8	17
34 " seven "	15	19
30 " eight "	13	17
25 " nine "	7	18
19 " ten "	10	9
16 " eleven "	5	11
8 " twelve "	4	4
4 " thirteen "	2	2
10 " fourteen "	2	8
3 " fifteen "	—	3
1 " eighteen "	1	—
1 " nineteen "	—	1
442	180	+ 262 = 442

¹ This table was made from Mr. Kingdon's reports of the City of London Truss Society for the years 1860 and 1861. It shows the ages of the individuals at the time of first discovering the hernia. M. Malgaigne states that inguinal hernia is even more common in females than crural. *L'Union méd.* 1854, p. 154.

² Report, 1860, pp. 10, 11.

By a preceding table the fact was demonstrated that crural hernia is most commonly developed between twenty years of age and forty. Now as we know that there is a much larger number of females alive between twenty and forty years of age than above forty, we might conclude that the number of cases of crural hernia is in proportion to the numbers of the population at any respective age. Under twenty years of age this is certainly not the fact, for the population at those early ages of life is of course the largest, whilst cases of crural hernia are exceedingly rare. The cause of the frequency of inguinal hernia during the early life of females has been before explained (p. 815).

It is highly interesting to compare the frequency of crural hernia at various ages with the numbers of the female population of London at the same periods of life; and in this inquiry we have made use of the census-table of 1851,¹ and Mr. Kingdon's statistics before alluded to. From those data the subjoined table is arranged:

		Crural hernia
Females under 20 years	403,260	38
„ from 20 to 40 years	453,809	432
„ „ 40 upwards	308,609	278
	1,255,678	748

This shows the number of cases of crural hernia in a million females—

Under 20 years to be	77
Between 20 and 40	952
Above 40	901

Doubtless this calculation can only be considered as approximating to numerical accuracy; but it seems to demonstrate the truth of the general proposition, that females between the ages of twenty and forty years are most liable to the development of crural hernia under certain conditions. The cause of this liability is probably due to the natural condition before alluded to, coupled with its attendant circumstances, and the occupations of the class of persons which would apply to public charities; as well as, perhaps, to configuration, and some predisposing causes, or hereditary influences.

Morbid states of the crural hernia.—An irreducible crural epiplocele is very often seen; an enterocele in the same state is very rare. With a view to ascertain whether the strangulation of the bowel was in any degree influenced by the accompaniment or absence of omentum, we made an analysis of sixty-one cases of strangulated crural hernia, which came immediately under our own care for operation. The proportions were equal; there being thirty-one pure enteroceles, thirty entero-epiploceles.

A reducible crural epiplocele may at any time become inflamed, give rise to local pain, and increase in size. The local application of cold, and absolute rest, are the measures to be employed to prevent adhesion between the rupture and its sac. This condition of an omental rupture in the groin is sometimes mistaken for angioleucitis. But the history of the case, and the negative evidence derived from the absence of every primary cause of lymphatic irritation, should suffice to remove all difficulty in diagnosis.

Both Pott and Astley Cooper allude to circumstances which are of vital importance in the treatment of crural hernia, viz. the difficulty often experienced in the reduction of small recently-developed enteroceles, the rapidly extending injury of the bowel, and the severity of the constitutional symptoms which are excited by that condition. But these features have been more fully insisted on by Mr. Bryant in a careful investigation of the cases admitted into Guy's Hospital.² Out of 142 cases of strangulated crural hernia, only 38 were reducible by the taxis. This, of course, is explicable by remembering that the majority of such cases is not sent to the hospital until the further use of the taxis is evidently unjustifiable. Ten of these cases were of recent development, that is, they were strangulated on their first recognised descent. This is an important feature in crural hernia, bearing especially on the results of treatment in these cases. It is cases of this kind which are so frequently over-

¹ Census, 1851, vol. i. p. 193, table ii.

² *Guy's Hospital Reports*, 1861.

looked by the medical attendant. He suspects that the symptoms exhibited by the patient are referable to a rupture, and he asks the question whether there is any tumour to be felt in the groin or elsewhere. Receiving a negative reply, he is content therewith. But that should not satisfy him. The surgeon should carefully examine the crural rings and the other regions in which a hernial tumour may exist.

The mortality arising in cases of strangulated crural hernia of all kinds is very large; but in those where the bowel becomes strangulated on the first descent, the death-rate is the largest. The experience of a large number of these cases teaches that the bowel should be liberated as soon as possible, and, if the taxis be not successful when the patient is fully under the influence of chloroform, that the cutting operation should not be delayed a moment.

The youngest girl we have heard of suffering with strangulated crural hernia was between eight and nine years old.

Application of the taxis.—The patient should lie on the back, with the hip-joint more or less flexed. The surgeon, taking a position most convenient for the purpose, gently compresses the whole swelling, at first endeavours to diminish its size by pressing any serous effusion that may happen to be in the sac into the abdomen, and next to empty the bowel of its contents. Then, recalling to mind the site of the crural ring, he presses the bowel backwards, inwards, and upwards.

The operation of liberating the strangulated bowel by incision.—The tissues to be divided to expose the sac are the integuments, the superficial fascia, the fascia propria, and often a layer or covering of fat. The points to be particularly observed as guides for the safe and certain manipulation of the sac are, first, Poupart's ligament in front and above it; and, secondly, Gimbernat's ligament at the pubic border of its neck.

Slight variation in the line, direction, or figure of the incision through the integuments is admissible, according to the inclination of the operator; but for all practical purposes we prefer a linear incision of from two or three inches in length. It should cross over the pubic side of the neck of the tumour, and extend on to the abdomen about one inch above Poupart's ligament. Its form being slightly concave, the neck of the tumour is embraced by the concavity. The integuments and superficial fascia being divided, a well-defined, membranous sac is usually seen, and the operator should next display clearly Poupart's ligament above the tumour, and feel Gimbernat's ligament to the pubic side of its neck. This covering is the fascia propria. Next, he may pass a hernia bistoury, with great care, between the last-named ligament and neck of the tumour, outside the fascia propria, and, directing its sharp edge upwards, cut a few of the fibres of Gimbernat's ligament, or of those which unite the falciform process of the fascia lata to it (Hey's ligament), and thus enlarge the crural ring. This done, the reduction of the rupture may sometimes be effected by the application of gentle pressure upon the contents of the sac. This proceeding constitutes the minor operation. It is simple, safe, and well adapted to cases of recent enteroceles which have been strangulated a very few hours, and when there is reason to believe that the bowel has escaped injury by the taxis. Obviously, therefore, it is only justifiable in select cases.

Failing to reduce the contents of the sac, the fascia propria is next carefully divided upon a grooved director, and a layer of fat is very frequently exposed. Inexperienced operators, mistaking this fat for the omentum, are puzzled when they cannot find the bowel, or they mistake the peritoneal sac for intestine when that is seen upon clearing away the fat. The hernial sac being exposed, it should be traced upwards to the crural ring, and the fascia surrounding it in the crural canal divided; or the division of the structures forming the crural canal having been reserved for this special moment, must now be undertaken, as before described. But the hernia remains irreducible. With great care, and *secundum artem* (p. 783), the sac must now be incised. Through the first puncture a stream of serum usually flows. Empty the sac of the fluid by enlarging the opening sufficiently to reach its orifice. If nothing but omentum be seen, carefully raise it from below or gently unravel it, and towards the mouth of the sac, secreted behind that part of the omentum which has just escaped through its mouth, the bowel will be seen. Next, to enlarge the

orifice of the sac, introduce the point of the finger between the protrusion and Gimbernat's ligament; but if that cannot be done, the hernia bistoury must be insinuated in front of the omentum, directing its cutting edge forwards and holding the blade parallel with the linea alba. Having then liberated the bowel from its constriction, it is easily returned into the abdominal cavity. It is not always necessary to cut the orifice of the sac, after having divided the tissues outside of it, as before described. Its tissues frequently yield before the gentle introduction of the finger.

Arrange the wound in such a manner that an opening exists at the lowermost angle for the escape of discharge, and flex the hip-joint by placing a pillow beneath the popliteal region for the limb to rest upon. Any further special detail for the treatment of the case is here unnecessary.

Mr. Kingdon has informed us that the extent to which Gimbernat's ligament is divided is a subject of grave importance as regards the future comfort of the patient. He states that Hey's ligament should rather be cut than Gimbernat's, and that when the latter is at all extensively divided, it is almost impossible to retain the hernia after the thickening, subsequent to the operation, has passed off. Certainly the most prodigious crural hernial tumours we have seen occurred in women upon whom an operation had been performed for strangulated bowel.

Arteries, cut during the progress of the operation, should be immediately twisted.

Wounds of the obturator artery.—This blood-vessel, when it passes to the obturator canal, after dividing from the internal epigastric or femoral, lies close to the neck of the sac, and it has been occasionally cut at the same moment as its orifice. Before using the knife, it might be practicable to feel the pulsations of this artery with the tip of the finger. When cut, an attempt should be made to arrest the bleeding by twisting the ends of the wounded vessel. See Mr. Spence's case, p. 818.

Omental sacs are most commonly met with in cases of crural hernia. An account of them has been given at pp. 783 4.

Obturator hernia. The obturator canal is situated at the upper and outer part of the obturator or thyroid foramen, and is bounded above by the horizontal ramus of the pubes, and in other parts by the obturator membrane or ligament and the obturator muscles, which are attached to its internal and external surfaces. The muscle within the pelvis is covered by the internal abdominal fascia, that outside by the obturator fascia. The obturator nerve, artery, and vein pass through the canal from the pelvis to the thigh. The course of the cutaneous filaments of this nerve should be especially noticed; for as its trunk is in close proximity to the hernial tumour, the pressure which the latter makes against it induces pain in those regions where the filaments of the nerves are distributed. In some cases this fact may prove a valuable aid in diagnosis, as the sequel will show.

This rare variety is described as hernia through the obturator canal, the foramen ovale, the thyroid or obturator foramen, and sub-pubic femoral. In the early part of the last century M. Garengot¹ called the attention of surgeons to this kind of hernia, which, after having escaped from the pelvis through the obturator canal, forms a swelling among the adductor muscles and in the pubic region of the thigh. The neck of the sac lies behind the horizontal ramus of the pubes, occupies the obturator canal, and makes its way sometimes between the uppermost fibres of the external obturator muscle, at other times above them. The fundus and body of the sac are covered by the fascia of that muscle. By the dissections of several cases, the obturator vessels and nerve are shown to be differently placed as regards the tumour. Vinson² states that he found the artery six times to the outer side of the sac, six times to the inner side, and three times behind it. The relative position of this artery to the sac probably bears some relation to its origin. In Mr. Stanley's case,³

² Gunther's *Lehre v. d. Nütigen Operationen*, Abschnitt xv. § 146.

³ *Trans. of the Path. Society*, vol. iii. p. 94.

both artery and nerve were above the hernial sac; the former to its inner side, the latter towards its outer.

Both sexes are liable to the formation of this hernia, but a large majority of the cases on record occurred in females. The anatomical reasons for this are obvious.

There are cases on record in which this hernia had existed, and in which the viscus was strangulated without any local signs of a tumour. Mr. Hilton's case,¹ in which the entire calibre of the ileum was in the sac; and Mr. Tebay's,² in which only a part was found, are marked illustrations. In Mr. Obré's case,³ 'the eye detected a slight degree of fulness in Scarpa's triangle,' and 'a distinct hardness could be felt, slight in its extent.' In the only instance we have seen, the hernia gave rise to a very distinct, well-defined tumour, deeply seated among the adductor muscles, to the pubic side of the femoral vessels. In Mr. Stanley's case,⁴ a crural epiplocele existed on the same side as the obturator entero-epiplocele. The latter was, however, extremely small, and produced 'no swelling on the inside of the thigh.' The hernia 'was found with its peritoneal sac beneath the obturator externus muscle, between the muscle and the obturator fascia.'

The foregoing observations illustrate the difficulties which attend the detection of protrusions through the obturator canal.

We have collected twenty-five of the most recently recorded cases of this variety of hernia, and the remarkable features they present are well worthy the attention of the reader. They may be divided into two classes: the first embraces a large majority, and consists of those cases in which the hernial tumour was not discovered during life; the second, those in which it was discovered by palpable examination, either immediately at the inner side of the thigh, or, as in one instance, only by an examination per vaginam.

In several of the cases of the first class, the tumour produced by the protrusion was so small, that the sac, with its contents, being placed deeply among the adductor muscles and beneath the pectineus muscle, could not give rise to any local external swelling. In two cases the tumour was found between the obturator ligament and obturator externus muscle. The contents of the sac in six cases consisted of only a portion of the calibre of the canal of the intestine. This had, however, become converted into a diverticulum, in some instances of considerable length. We met with this condition of the hernia occasionally in other regions, but the cases are not common; and we may therefore conclude that, in proportion to the rarity of obturator hernia, this may be considered to be one of its remarkable features. In one case, the Fallopian tube and ovary formed the contents of the sac; in another, a portion of the urinary bladder.

The hernial sac, which is never wanting, consisted always of a portion of the parietal peritonæum of the pelvis thrust through the canal, and tolerably firmly attached to the parts with which it was in contact. The sac was therefore slowly formed. On this account some of the patients had experienced, during the development of the hernia, repeated attacks of bowel derangement, evidenced by symptoms of obstruction, termed colic pains, uneasiness at the inner and upper part of the thigh, and even cramp or spasmodic pains in the muscles of the femoral region, and which extended down the leg.

In a large number of the cases, the acute pain in the course of the obturator nerve, described by the patient, was a marked feature of the case, and pressure over the site of the external aperture of the obturator canal gave rise to paroxysms of pain of great severity. It is due to the tact of Mr. Howship⁵ to state, that he seems to have been the first writer to dwell particularly upon this fact, which some years afterwards was strongly insisted upon by Romberg.⁶ The only patient we have seen with this variety of hernia complained bitterly of feeling a sudden pain at the upper

and inner part of the right thigh, which extended thence down the inside of the limb to the knee, front of the leg, foot, and great toe.

The cases of the second class are those in which the tumour was discovered during life, either in consequence of its bulk, or by a careful examination of the region in which it was developed.

Dr. Roeser¹ proposed that advantage should be taken of the rectal passage of the male, and the vaginal of the female, to institute a more searching examination of the obturator region within the pelvis; and by this means Dr. Lorinser, in 1857, discovered an obturator hernia.² Dr. Nuttall, of Leicester, in the same year, in a case in which not even fulness of the adductor fossa was perceptible, was induced, by the severity of the constitutional symptoms of strangulated bowel, and the pain caused by local pressure made directly upon the obturator region, to explore that part; and his judicious treatment was rewarded by the discovery of a very small hernial tumour, the contents of which were returned into the abdominal cavity by gentle pressure, without incision of the sac.³ Before this Mr. O'bré had successfully operated upon a case of strangulated obturator hernia in 1851, in which 'the eye detected a slight degree of fulness in Scarpa's triangle, on the right side; this triangle of the opposite limb being well marked with a hollow or depression passing down its centre, but which was lost on the affected side. Also, on pressing firmly a little below the saphenous opening, a distinct hardness could be felt.' Lastly, in the case successively operated upon by Mr. B. B. Cooper, in 1853, the woman being very thin, there was both ocular and palpable evidence of an indisputable nature. At first sight, the swelling in Scarpa's triangle seemed to be identical with that which might be produced by a protrusion through the crural canal; although it had not the appearance of being in close relation with Poupart's ligament, for it formed a somewhat globular fulness, rather than a circumscribed tumour. Then the point of the finger could be placed in the crural ring, which, of course, was conclusive evidence that the hernia had not escaped through it. Really, therefore, there were no practical difficulties to prevent the formation of a correct diagnosis in this case. We may here state that these observations are made from notes of the case taken personally at the bedside of the patient.

Complications.—But we must allude to a class of cases, of which there have been several instances, in which the existence of an obturator hernia was complicated with the development of other kinds, especially those in the inguino-femoral regions. In one case there was a reducible crural hernia on either side; in three cases, a crural hernia on the same side as the obturator; in one case, on the opposite side; and in another case, an inguinal hernia on the same side as the obturator.

The treatment adopted in three of these cases was that which most surgeons would approve. The symptoms of strangulated intestine being clearly marked, an exploration was made of the hernial sacs, which were visible and tangible, in the expectation of finding a small knuckle of bowel retained within them. But nothing of the kind being found, the examination was not prosecuted further; although, in two of the cases, an obturator hernia, seated immediately beneath the site of the operation, was proved, by after-death examination, to have been the cause of death.

As a possible complication, we must here allude to the fact that in some of the cases, in the same individual, a sac was found to pass through both right and left obturator canals.

In fourteen of the cases the obturator hernia was not discovered until after death. In one case the symptoms indicated the existence of this variety of hernia, and the patient recovered without any interference on the part of the surgeon. In ten of the other cases the protrusion through the obturator canal was discovered during life; and the treatment adopted and its results we may briefly describe. In one case the protrusion was reduced after the application of the taxis by Dr. Roeser, of Bartenstein. This was in a female 30 years of age, rather corpulent, who had been frequently troubled with intestinal disturbance. By careful manipulation a small tumour was felt over the external aperture of the left obturator canal, upon which pressure caused great pain.⁴ In another case Dr. Roeser was not so successful in the treatment. This was a male 50 years old, who had been frequently troubled with pains in the abdomen, called colic. The case was rendered obscure by enlargement of the inguinal glands on the same side as the hernia; nevertheless Dr. Roeser diagnosticated the obturator rupture and partially reduced it. The man, however, died, and after death a part only of the wall of the intestinal tube was found in the sac.⁵

In one case the obturator hernia was discovered during life after the performance of gastrotomy.¹ Dr. Arntz saw a woman 62 years old when she had been suffering three weeks. He discovered and diagnosed an obturator hernia, the integuments over which were inflamed and becoming gangrenous. He made an incision; the contents of the tumour escaped; and the patient died next day.² The accuracy of the diagnosis was verified after death.

Dr. Heiberg operated upon a woman, 50 years old, after distinctly feeling an elastic swelling in the left adductor region. Upon this tumour he cut down, opened the hernial sac, stretched the obturator canal with his finger, and returned the bowel. The patient, however, died.³ Mr. Heath, of Newcastle, operated upon a woman 75 years old. The tumour, although small, was perceptible; the pain on pressure and down the limb very characteristic. The aged patient survived the operation thirty-six hours, and the commencement of the attack about four days.⁴ Dr. Nuttall, of Leicester, being called to a woman, aged 75 years, suffering with well-marked indications of strangulated intestine, but without any tumour in the usual site of hernial protrusions, was led, in consequence of pain being produced in that part when he pressed in one particular spot, to diagnose an obturator hernia, although there was not even 'fulness' perceptible, over the site of the obturator region. He cut over this painful spot, found a small tumour, exposed the hernial sac, and reduced its contents by gentle pressure. This old woman survived thirteen days. After death the bowel which had been strangulated was found in process of repair. An obturator hernial sac was seen on both sides.⁵

We have now to describe the cases which have been cured by operation. The late Mr. Obré, of London, was the first surgeon to cure a case of strangulated obturator hernia. This was in 1861. In a woman, aged 55 years, tall and stout, he diagnosed this hernia. He cut down upon the swelling, incised the sac and its orifice slightly, and returned a small piece of blue congested bowel.⁶

In 1853 I assisted Mr. Bransby Cooper in an operation he performed at Guy's Hospital on a woman, 49 years old. She was exceedingly emaciated, had given birth to twelve children, and was affected with bronchitis. She was not aware of being ruptured. For sixty-two hours before coming to the hospital she had been suffering with strangulated intestine. Her illness began with a sudden pain at the upper and inner part of the right thigh, and extended from that spot along the inside of the thigh, knee, front of leg, and to the great toe. Upon examination of the region below Gimbernat's ligament, a deeply-seated swelling was felt. Mr. Cooper made an incision over the tumour, divided the pectineus muscle, and reached the hernial sac. Gentle pressure was made upon it, and the contents passed readily into the abdomen. She slowly recovered, and the wound entirely healed; but before she left the hospital she was seized with acute bronchitis, which caused her death.

Dr. Lorinser, in 1857, discovered an obturator hernia by an examination per vaginam. The age of the patient is not stated. On the eleventh day after the commencement of the attack, he cut down upon the tumour, opened the sac, and found the contents in a state of gangrene. A fæcal fistula was established, which subsequently closed, and the woman survived the operation eleven months.⁷

We have now given a brief but instructive summary of the cases on record from which useful practical lessons may be derived. There are more instances published, which have been discovered after death, and therefore simply attest the fact of the existence of the disease.

Mr. Kingston believes he has met with five cases of obturator hernia in living persons. Two of them were in men; in both the femoral artery was in front of the swelling, and pushed forwards at each forced expiration. The men were past forty years of age, thin and gaunt. He does not recollect whether the femoral artery was pushed forward in the female, whose case he otherwise well remembers, but he distinctly recollects that he was able to feel the bony rim at the upper edge of the aperture, through which he had returned the hernia. The woman was emaciated to the last degree of voluntary locomotion.

We propose next to select the most prominent facts from the whole number of cases, with an especial view to the diagnostication of those cases in which there may not be any palpable or ocular evidence of a rupture.

Diagnosis of an obturator hernia—from its position. After passing along the obturator canal, it emerges upon the thigh below the horizontal ramus of the pubes, to the inner side of the capsule of the hip joint; behind, and a little to the inner side of the femoral artery and vein; and to the outer side of the tendon of the adductor longus. The tumour formed by the protrusion is covered by the pectineus muscle. From crural hernia, therefore, it may be distinguished by observing the

⁷ Gunther's *Lehre v. d. blutigen Operationen*, Abschnitt xv. § 147.

relative positions of the horizontal ramus of the pubes and of the femoral artery. Those structures occupy, in fact, a position between these two kinds of hernia. In obturator hernia they are in front of the tumour; in crural hernia they are behind it. In the former, then, they are easily felt; in the latter they cannot be without difficulty—not, perhaps, until the hernia be reduced. In those cases in which either a fulness, slight hardness, tumefaction, or swelling exists, coupled with well-marked indications of obstruction or strangulation in some part of the alimentary tube, the difficulty of diagnosis is not so very great; but how much embarrassment arises when those symptoms which betoken strangulated bowel exist, and a tumour is nowhere to be felt, let the numerous cases on record attest, in which the rupture has only been found after death.

Assuming, for the sake of illustration, that we have before us a patient suffering with well-marked constitutional indications of strangulated bowel, and that, after the most careful examination of all those apertures through which ruptures more commonly escape, we have failed to detect any palpable tumour to assist in explaining them, how are we to discover an obturator protrusion, or obtain sufficient evidence of the probable existence of one to justify an exploration of the obturator region by means of the scalpel? We reply, By pain during the development of the hernia; by pain at the commencement of the present attack; by pain of a peculiar character during the progress of the illness; by pain referred to the course of the cutaneous filaments of the obturator nerve and the plexus formed with it, and the internal cutaneous and its distributions; by pain excited by certain definite movements of the hip joint; by pain induced by local pressure carefully applied; and by pain when an examination of the pelvic orifice of the obturator canal is made per vaginam.

We shall now describe these important indications with a little more precision. During the formation of the hernia, some of the patients had suffered at irregular intervals with constipation, nausea, and pain resembling colic in the pelvic region; and one woman related how upon repeated occasions she had suffered thus, and felt relieved directly after experiencing a sensation as if something slipped back into the abdomen at the lower part. In Mr. Hilton's case, some months before the fatal attack from hernia on the left side, the patient had suffered with symptoms of bowel-obstruction and pain referred to the right side. After death a right obturator hernial sac was found, 'more distinct than on the left side, large enough to admit freely the forefinger.'

One patient narrated, in a very striking manner, how she had been suddenly seized with a violent pain at the inner and upper part of the thigh. Soon afterwards, nausea, followed by vomiting and all the other indications of strangulated bowel, existed.

In several of the cases there appears to have been something very characteristic in the nature of the pain. Admitting the difficulty of meeting with any two or more persons who would describe pain so closely resembling each other's sensations as to prove an infallible guide, yet that described during the progress of the illness seems to afford some clue in these cases. It is described as spasmodic contraction of the abdominal muscles, and not as pain within the abdomen. For the explanation of this phenomenon, we may refer to the association existing between the cutaneous filaments of the obturator nerve, which are irritated by the pressure of the tumour in the obturator canal, and the muscular filaments distributed in the abdominal muscles; for all are branches of the lumbar plexus.

The pain described by several patients, in both instances, when a hernial tumour was palpable, as well as when it was entirely concealed, could not have failed to attract the notice of the surgeon to the distribution to the cutaneous filaments of the obturator nerve, and the more internal of the internal cutaneous. In this fact we have a most valuable aid to the diagnosis of some abnormal pressure upon its trunk, as it traverses the obturator canal. Certain definite movements of the hip-joint may subserve very usefully in diagnosis, as, for example, when there may be some doubt on which side the protrusion exists, or when it chances to be so small as to be under the influence of the obturator muscles, when only in a violently contracted

state. We may therefore employ the actions of these rotators of the femur outwards, to compress the tumour, and thus excite pain; and by comparing the influence of these muscles on both sides of the pelvis, valuable aid might be obtained. It has been demonstrated after death, that in some cases the protrusion passes between the fibres of the external obturator; and therefore we may suppose that they could readily compress the neck of the tumour. Want of space prevents further detail; we must therefore leave the adoption of this test, and the method of employing it, to the intelligence of the surgeon.

In several cases, the effect of local pressure over the external outlet of the obturator canal has been to cause acute pain, and even the detection of slight fulness or hardness when no other sign existed at the site of the protrusion. But even this examination should be made with great discrimination. A careful distinction must be made between pain caused by pressure on the obturator nerve and on a hernial protrusion; the muscles, especially the pectineus, must be relaxed; and a comparison of the results of the same amount of pressure on the two sides of the body in the same locality should be instituted with proper precautions. The femur should be supported by an assistant in a position of slight flexion, with rotation outwards, and between abduction and adduction.

The pelvic aperture of the obturator canal may be reached from the vagina in the female, and from the rectum in the male. In cases of difficulty and doubt, therefore, some assistance may be gained by taking advantage of the opportunities these passages afford for the necessary examination.

Accuracy in diagnosis being of paramount importance, we cannot conclude this part of the subject without alluding to the great advantage to be derived from carefully comparing the outline of Scarpa's triangle on both sides of the body; and of impressing upon those who may happen to have a case of suspected obturator hernia under examination, the practical value of seriously reflecting upon all the features of the case referable to nervous derangements, as aids to diagnosis in these most perplexing and difficult cases.

Treatment.—Should a hernia be detected, the application of pressure to the tumour may succeed in reducing it. The pressure should be directed in such a manner as to free the hernia from the ramus of the pubes, and pass it underneath it.

Failing to do this, or even with a well-grounded suspicion of hernia, the surgeon should explore the region below Poupart's ligament. The incision through the integuments should be either parallel with the trunk of the femoral artery, or with the fibres of the adductor longus muscle. It must be sufficiently far inside the artery to avoid the femoral vein. It may commence a little above Poupart's ligament, at a point midway between the spine of the pubes and the spot where the femoral artery passes over the ramus of that bone. The fascia covering the pectineus muscle being exposed, perhaps the hernial tumour may be felt; and if not, pain on local pressure may incite to a deeper prosecution of the search. This fascia and the pectineus muscle being divided in the line of the original incision, or its fibres being separated with the handle of the scalpel, some fat and the fascia of the obturator muscle are reached. As yet, however, the tumour has not been felt; nevertheless it may still be there, under cover of the fibres of the obturator muscle. These must be separated; for it is not until the finger can be placed upon the outlet of the obturator canal that the search for the hernia should be abandoned as hopeless. Care must be taken to avoid cutting the filaments of the obturator nerve.

How far the surgeon would be justified in making an examination of the opposite side, after having failed to find the hernia on the one first explored, is a proposition we must leave to the judgment of those who may happen to be placed in such an unpleasant dilemma.

We conclude with this observation of Camper: '*Forsan frequentiores sunt, quam quidem creditur; in illo igitur ad omnis generis herniarum possibilitatem necessario attendendum est.*'

Perineal hernia.—The sac of this hernia is formed of the peritonæum, which in the male lies between the prostate gland and rectum, and in the female between the vagina and rectum. In both sexes, when the hernia fills the sac, there is a tumour in the perinæum. This kind of hernia is most common in women, and usually consists of a portion of the alimentary canal, of the omentum, or of the urinary bladder.

The sac of a perineal hernia escapes between the anterior fibres of the levatores ani, and is covered by the internal abdominal fascia of that region of the pelvis.

The protrusion of the hernia may be prevented by using a T-shaped bandage.

Pudendal hernia.—Pudendal hernia forms a small elastic tumour in the labium pudendi. It lies in the posterior and inferior half of that organ, and forms a somewhat elongated projection at the side of the vagina. The neck of the sac is placed between the ascending rami of the ischium on the outside, and the vagina on the inside.

This hernia may be developed at the age of 22 years (Sir A. Cooper); and in this case it had existed some months.

The tumours in the labium, which may be confused with this hernia, are those formed by inguinal protrusions and collections of fluid. Of the last are cystic formations and hydrocele of the round ligament. These, however, are never reducible; they are not diminished by pressure, and they slowly increase in size from their first appearance.

From inguinal hernia it is distinguished by its position, shape, and relations. It has not passed through the external inguinal ring, but lies parallel with the axis of the vagina. It does not form a pyriform tumour in the labium, but a somewhat rounded mass. It lies by the side of the ramus of the ischium, and not over the body of the pubes.

From crural hernia it is distinguished by the neck of the tumour being placed entirely to the inside of the ramus of the ischium, and the muscles attached thereto.

A suitable bandage is required to support the protrusion.

Vaginal hernia.—This hernia is usually developed in women who have borne several children. It is only covered by the peritonæum, and that portion of the walls of the vagina which protrudes. The orifice of the sac is usually large, and readily yields to pressure. Consequently it is easily reduced, and, with the exception of the discomfort and annoyance it causes, it is not attended with urgent symptoms. The rectum and urethra may, however, become so much compressed, that inconvenience and sometimes suffering may arise from this cause.

The protrusion requires to be replaced in the pelvis, and the necessary support to maintain it there is afforded by making use of a suitable bandage.

When the urinary bladder forms the rupture, which occasionally happens, great distress arises from a constant desire to micturate. The urine becomes ammoniacal, and the bladder so irritable, that a few drops of urine, constantly escaping, cause intolerable inconvenience. Treatment is therefore urgently required to improve the condition of this secretion, and to empty the bladder, whilst the rupture must be at the same time supported.

Ischiatic hernia.—This kind of hernia escapes through the ischiatic notch, and forms a tumour beneath the glutæus maximus muscle. The neck of the sac is either above or below the pyriformis muscle, but generally below it. The fundus, at first covered by the glutæus muscle, as it extends further out of the pelvis, escapes below the edge of that muscle, and lies under the integuments.

When the hernia is in the sac, it forms a tumour of variable size, soft, tense, yielding, reducible on pressure, and causing more or less pain.

Should the hernia become strangulated, and the operator be required to enlarge the mouth of the sac, Sir A. Cooper advises that the incision be carried directly forwards.

DISEASES OF THE RECTUM.

IN the following essay on Diseases of the Rectum I have treated the subjects in the order of their frequency and importance: Hæmorrhoids; Prolapsus; Fistula; Ulcer; Stricture; Cancer; Polypus, Pruritus, and Neuralgia. Nothing has been said in reference to malformations of the anus and rectum, as this subject is considered in the essay on the SURGERY OF CHILDHOOD.

HEMORRHOIDS.

It has been the custom of surgical writers, when describing hæmorrhoids, to divide them into two distinct kinds, namely, external and internal. This is a classification from which it is perhaps not well to deviate; for, although many instances are seen where it is impossible to say whether the disease be internal or external—and, pathologically speaking, hæmorrhoidal tumours, wherever situated, are essentially constituted of the same morbid elements, viz. an enlargement of the vessels of the rectum, and an infiltration of their connecting tissues—still circumstances which exist, or which occur, in connection with this disorder so modify the pathological features, that in numerous instances there is a wide and well-marked distinction between those hæmorrhoidal tumours seated outside, and those involving the gut within the sphincter.

I shall therefore adhere to the classification, and first speak of

External hæmorrhoids, which are situated at the verge of the anus outside the sphincter, and consist of one or more tumours, composed at their first formation of dilated vessels. As the disease increases, from various irritating causes, the sensitive skin around the anus becomes thickened, the cellular tissue is indurated and infiltrated, and the veins are expanded. By degrees the swelling becomes larger and harder, and does not give much annoyance when the parts are in a quiescent state; if, however, they become attacked with inflammation, the tumour increases much in size, the blood in the vein becomes coagulated, and not unfrequently the vessel gives way, allowing the coagulated blood to escape into the surrounding cellular tissue, where it will form a distinct sheath for itself. In the course of time the inflammatory action subsides, the blood becomes absorbed, and the tumour diminishes in size, or wholly disappears. If, however, the same irritating causes recur, and no effectual treatment be adopted, the tumour again increases, the skin becomes thickened, and the cellular tissue more extensively infiltrated; and in this way distinct and permanent tumours are formed around the anus, which sometimes reach a large size, consisting mainly of thickened integument and cellular tissue enclosing veins which are at times capable of distension and repletion. In their quiet state these tumours are distinctly external; but when increased in size they may encroach upon the cavity of the rectum and be covered with mucous membrane and thus be partly internal. Coexistent with this state there is not unfrequently a very œdematous condition of the cellular tissue and mucous membrane at the verge of the anus.

With regard to the actual structure of these hæmorrhoidal tumours, it will be found on examination that they are composed of thickened integument, infiltrated cellular tissue, and in most cases of one or more dilated veins; if the part is at perfect rest and has not been lately inflamed, there may be distinguished nothing beyond infiltrated tissue and thickened skin; but on cutting into an external pile which has been somewhat irritated, or is increasing in size, there will be found either a vein considerably dilated and containing semi-coagulated blood, or the blood will have escaped from the vessel, and have become either extravasated into the

surrounding cellular tissue, or have formed for itself distinct cellular sheaths. This coagulation of the blood is the reason why an incision into an external hæmorrhoidal tumour, after having become inflamed and swollen, is scarcely ever attended with bleeding, and it is one of the main pathological features in this form of tumour, and far different from what obtains in instances of the internal affection.

These external hæmorrhoids vary much in size, the swellings being sometimes not larger than peas, while at other times they are the size of a walnut. Their presence is accompanied with unpleasant symptoms: as irritation; pain when at the closet; and a sense of bearing down, even when they are in a quiescent state; but the main source of suffering is their disposition to become suddenly enlarged and inflamed; which occurrence will arise from allowing the bowels to become constipated, from the straining attendant upon a stricture of the urethra, from excess in food and drink, or from exposure to damp and cold. Under these circumstances, the tumour, which has been hitherto small and flaccid, becomes much swollen, distended, and livid in colour. From the peculiarly sensitive character of the skin at the anus, this distension is accompanied with the most exquisite pain; and it is remarkable to witness the complete prostration with which the most powerful man is overcome when suffering from acute inflammation of external piles, and especially when the symptoms have been allowed to go on for some days without the proper means of relief being afforded, either from obstinacy on the part of the patient, or from insufficient pathological knowledge on the part of the medical attendant.

With regard to the causes which produce this form of hæmorrhoids, there is every reason to believe that the same circumstances which tend to the production of external, induce the internal affection as well; and therefore this description will apply to both. It appears that there is in some persons an hereditary disposition to hæmorrhoidal affections; and we shall every now and then see father and son, or mother and daughter, suffering one after the other in the same way. Possibly, however, this may be owing to similarity in habits, certain of which undoubtedly much more than others induce these affections. Thus, those who have to sit continually at the desk, and take little walking exercise, are very liable to them; those, too, who have to stand long in certain positions, as dentists and hairdressers, are remarkably prone to hæmorrhoids. The great source of hæmorrhoidal affections, however, is anything which prevents the healthy return of the blood from the vessels of the rectum. And thus it is that congestion of the liver, or other obstructive disease of the same viscus, is frequently associated with these affections. A constipated state of the bowels, both from the mechanical effect produced upon the vessels, and from the straining efforts necessary, is found to be the cause in a vast number of cases; the pressure also of the pregnant womb, and of ovarian tumours, produces hæmorrhoids. In other cases, the irritation caused by the frequent taking of aperient medicines is reasonably considered to be productive of the first symptoms of the disease. Violent horse-exercise, indulgence in the use of highly-seasoned dishes, and other indigestible food and strong wines, together with immoderate sexual intercourse, which determines the blood more freely to the pelvic region, are each fertile sources of hæmorrhoidal affections. And it is highly necessary, before any treatment is commenced, to inquire carefully into the peculiar habits of the patient.

The treatment which should be adopted for the removal of this affection must be conducted upon the ordinary principles of surgery. In the more simple cases, little beyond a strict attention to ablution, to the regular action of the bowels, and to the avoidance of those causes which are known to produce the affection, will be necessary. If there be much irritation about the anus, an occasional dose of calomel should be taken either before or in conjunction with aperients. At the same time that great care is taken to provide a healthy action of the bowels, local remedies should be made use of. The ordinary lead-lotion, or one made of one or two grains of sulphate of zinc to an ounce of water, should be applied to the parts morning or night; or if a more powerful astringent application is required, the patient should use the compound gall ointment, which is an admirable agent. By these means, and by

careful attention to diet, most of the ordinary cases of external piles presented to our notice may be cured, or so relieved that they will hardly excite attention.

If, however, one or more of these tumours become enlarged and inflamed, a much more energetic treatment is required; for there is in such cases very great suffering both local and general. If there is much swelling, and the parts are exquisitely sensitive, the patient must be confined to bed, leeches should be applied to the part, and the bleeding be encouraged by warm fomentations; and subsequently poultices made either of warm bran or of bread, into which half a drachm of laudanum is dropped, should be applied, and changed from time to time. Opium should be given internally; as soon as relief from pain has been procured, the bowels should be thoroughly cleared by a saline purgative. The subsequent employment of a lotion composed of liquor plumbi diacet. dil., liquor ammoniæ acetatis, and spirits of wine—one ounce of each of the latter to six ounces of the former—will cause a shrinking and collapse of the swelling.

Not unfrequently, however, the surgeon is called to a case where most or all of these measures have been tried, and yet the patient is suffering acutely; and on examination it will be found that on one side of the anus there is a tumour of a circumscribed form, of a blue colour, and in a state of great distension. In such an instance, the suffering is produced by the accumulation and coagulation of the blood; and the proper treatment is to puncture the swelling freely with a lancet: there is an escape of coagulated or semi-fluid blood, with almost immediate relief to the painful symptoms. The subsequent application of cold water, or the lotion above mentioned, to the parts freely, will cause an almost entire removal of the disease. If, however, there is much loose and thickened skin over the site of the swelling, it should be removed with sharp scissors, after the part has been punctured.

After repeated attacks of this nature, the anus becomes surrounded with distinct tumours, more or less pendulous, and liable to become swollen and inflamed; for this state of things a removal of the growths by the scissors is required.

Simple as this operation is, it may in unsurgical hands be so mismanaged as to bring about serious results. If too much of the lax skin around the anus be taken away at the same time that the tumours are excised, the parts in healing will cicatrize, so that severe contraction of the anus follows, and the patient is placed in a most miserable plight.

The same effect is likely to be produced if the mucous membrane at the verge of the anus is interfered with to any great extent: therefore, unless there is an absolute necessity for the step, this membrane should not be cut, and only the external hemorrhoids, with portions of the redundant integument, should be excised.

Internal hemorrhoids are more frequent, or at all events are more often presented to the notice of the surgeon, because they are productive of much more distress, and more serious consequences are liable to result from them than from the affection situated externally: and here it will be as well to mention the symptoms which are produced by them, and which are local and general.

The first local symptom which attracts the notice of a patient suffering from internal piles is, in many cases, a more or less profuse attack of hæmorrhage, which may not recur for some weeks or months, but which may persist: more or less weight and uneasiness are felt at the seat; and in course of time there will be pain when the bowels are being evacuated and considerable protrusion of the parts will take place. If the patient neglects advice, the tumours come down below the sphincter whenever he takes walking exercise, the constriction caused by the muscle produces congestion in the piles and extreme pain, only relieved by their reduction or by a spontaneous flow of blood, which, however, occurs at most inopportune periods. In addition to these symptoms, there is pain and uneasiness felt in the loins and down the thighs, more especially in females, who very often suffer most acutely, and not unfrequently have their sufferings referred to that prolific storehouse of morbid phenomena, the womb. There is, moreover, a considerable discharge of mucus, or

mucopurulent fluid, from the anus; the bladder is rendered at times very irritable, and retention of urine not unfrequently takes place.

Patients who suffer from internal hæmorrhoids are liable to get them inflamed from some exciting cause, such as an excess at the table, or great irritation of the bowels, and then the symptoms are extremely severe; the tumours protrude beyond the anus, and become constricted by the sphincter. Violent pains are experienced in the pelvic region, and there is a high state of constitutional disturbance, denoted by flushed face, furred tongue, rapid and wiry pulse, and extreme restlessness. If these symptoms are not relieved either by the accidental induction of bleeding, or by surgical assistance, the congestion and inflammation increase, and to such an extent that mortification of the hæmorrhoidal masses ensues, and thus is produced a natural cure; but, on the other hand, it is not desirable to encourage this rude attempt at cure, for death may occur from the violent action set up. Dr. Bushe mentions having seen such a case occur.

When internal hæmorrhoids have existed for a length of time, the general health becomes much influenced; the patient complains of indigestion, flatulence, an inability to follow his ordinary occupation or amusement; moreover, if, as is frequently the case, the disease be attended with periodical bleedings, the face becomes blanched, the pulse weak and rapid, and other well-known symptoms of loss of blood ensue. This is the most serious condition connected with hæmorrhoids of long standing, and hence the reason why it is most important to adopt the proper treatment at an early period of these affections.

Internal hæmorrhoids present various appearances. On making an examination of a patient who suffers from the milder form of the affection, the veins of the lower extremity of the rectum just within the anus will be found enlarged and distended, forming small fusiform tumours of a deep blue colour covered by a somewhat thickened mucous membrane. In other instances, and especially where the patient complains of bleeding and sense of weight, with scarcely any protrusion, the inferior extremity of the rectum, for an inch or more, will be found highly congested and vascular, the mucous membrane having here and there distinct patches of morbid vascularity, from which, through a speculum, which it is necessary to use in such cases, blood of an arterial colour will be seen to issue. This is the condition which the late Dr. Houston, of Dublin, likened to the diseased lining membrane of the palpebræ in cases of chronic conjunctivitis. In the majority of instances, however, of internal hæmorrhoids, one or more distinct tumours of a rounded or oblong form will be seen to fill up, as it were, the orifice of the anus. In some cases their character and size can be ascertained by an ordinary inspection; but it is always best, in order to arrive at a proper diagnosis, to throw up an injection of warm water, and allow it to be discharged before the examination is made. By this means the tumours are brought fairly down. There are frequently two or three distinct tumours, varying from the size of a cherry to that of a walnut. In one case, the diseased part presents a bright red appearance, easily bleeds when touched, is sessile and not very raised; in another case, the tumour is large, prominent, of a deep blue or reddish-brown colour, having a large broad base, or being attached by a narrower peduncle, and does not

FIG 170.—Internal Hæmorrhoids surrounded by External Hæmorrhoids.

bleed. In these cases the vessels appear to be largely dilated, the mucous membrane covering them being shining and tense, or thick, granular, and slightly ulcerated. Besides these appearances, portions of the mucous membrane, highly vascular and thickened, may be prolapsed at one or more points, as a consequence of the mechanical weight of the internal tumours. In by far the majority of cases of long-standing piles, the integument surrounding the anus is in an unhealthy condition, being much thickened and now and then forming a distinct ring or long pendulous flaps.

There is one point of importance connected with the seat of internal hæmorrhoids which should not be overlooked, but which, as far as I am aware, has not been mentioned by any writer on the subject. The circumstance I refer to is this, that occasionally instances are met with where the hæmorrhoidal tumours are placed, as it were, in separate rows, so that two or three distinct masses exist near the anus; and about half an inch or more above, other tumours of a similar nature are disposed just in the same way. There are one or two specimens indicating this in the Museum of the Royal College of Surgeons. This is a condition of practical importance; for it shows how necessary it is to make a most thorough examination of a person suffering from internal piles. Cases every now and then occur where the ligature has been applied to one or more internal tumours presenting themselves at the anus; and as the operator is thinking his proceedings are satisfactorily terminated, the patient makes some violent straining effort, and another tumour, or series of tumours, which have escaped notice hitherto, are forced into view. These are formed higher up in the bowel, and do not generally protrude; but if a satisfactory cure is expected, they must not be left alone.

As regards the structure of internal hæmorrhoids—when first forming, they are composed in many instances simply of dilated veins, in others of dilated veins and arteries too. As the diseased condition increases, the cellular tissue in connection with the vessels becomes thickened and infiltrated. In a more or less circumscribed space, the mucous membrane also becomes thickened, and is bulged out by the increase in size of the vessels, and thus distinct tumours are formed. The surface of the mucous membrane becomes also exceedingly vascular. On making a section of the lower part of the rectum in some cases of old-standing piles, the veins will be found to be greatly dilated, sometimes partially and irregularly; so that there will be the appearance of distinct cysts; in other instances, the dilated vessels will be found to be filled with coagulated blood and fibrin. In those cases where the hæmorrhoids are of a very bright red colour and sessile, not unlike a strawberry in appearance, and easily bleeding, the structure consists mainly of a series of small arterial ramifications; but where the tumours are of a darker colour, and like a mulberry, they are composed of veins to a large extent, although no doubt the arteries enter as well into their formation; for when the mucous covering is pricked or incised, the blood which flows is of an arterial hue. In those cases of long standing, where the tumour has become very large, and has been submitted to great irritation, a section will reveal scarcely anything beyond a mass of highly-condensed and thickened cellular tissue, with some vessels penetrating the base of the tumour.

The treatment of internal hæmorrhoids requires more consideration than that which is adopted for the disease when situated externally. In the cases where the piles have not existed long, are not large, and give only temporary annoyance, much may be done by the patient paying simple attention to his habits, and avoiding those exciting causes which engender the disease. If it is ascertained that a sedentary life has produced the affection, by determining the blood to the rectum, the patient should take as much walking exercise as possible; if the bowels are sluggish, their action should be encouraged by the compound rhubarb-pill, or by a teaspoonful of the confection of senna; and a quarter or half a pint of cold water, or of infusion of quassia, should be thrown up the rectum daily. Dietetic rules must be strictly attended to; for many patients, especially those who are robust and whose circulation is sluggish, will tell us that they feel much more annoyance from piles after they have been dining out, or have taken larger quantities of wine than usual. Hence the necessity for those who suffer from internal hæmorrhoids to abstain as much as

possible from the pleasures of the table. Women in an advanced state of pregnancy suffering from the irritation of piles should be very careful about the condition of their bowels, and should keep the horizontal posture as much as possible.

When internal hæmorrhoids increase to such an extent as to protrude at the closet, and produce considerable pain and bleeding, greater precautions and more decided treatment are needful. The bowels should never be allowed to become costive so as to necessitate straining efforts; the protruded parts should be carefully sponged with cold water, or with a strong infusion of quassia or of decoction of oak-bark and alum in the proportion of half a drachm of the salt to twelve ounces of the decoction, and should be carefully returned by the patient; or, instead of these lotions, the gall-ointment may be smeared over the piles with great benefit. The bleeding, which is often very annoying, may be checked by an injection of sulphate of iron and water, in the proportion of one to two grains of the former to an ounce of the latter; or, if necessary, a lotion of tannin, in the proportion of eight grains to an ounce, may be used; but it must be borne in mind that a moderate amount of bleeding in persons who live high, and whose vascular system is excited, is beneficial rather than otherwise, and should not be interfered with; the popular notion as to bleeding from piles being salutary is by no means incorrect, when applied to certain cases. When, however, the hæmorrhage arises from some peculiar pathological change in the tumour, such as ulceration or excessive vascularity of the mucous membrane, and when it becomes continuous and goes on to such an extent as to interfere with the patient's health, producing a pallid face, a weak pulse, and irritable heart, it should be put a stop to.

A very common internal remedy for piles is the confection of black pepper, in the dose of a drachm twice a day; it may be given by itself, or, as I often use it, mixed with an equal part of confection of senna. It is difficult to say how the remedy acts; it certainly does good not only in this affection, but it is highly serviceable in other affections of the rectum, and especially in those cases where the wounds become sluggish in healing after the operations for fistula, or for fissure of the anus.

When internal piles become inflamed and protruded beyond the sphincter, the patient will suffer much both locally and constitutionally. He must be confined to bed, and the piles, if possible, should be carefully returned by the surgeon; but if this be a work of great difficulty from swelling and congestion, leeches should be applied, and subsequently warm fomentations and poultices. Ice locally applied in a bladder is a valuable agent to diminish inflammation and pain. Opium should also be given in full doses. An operation which may be considered advisable should not be put in force whilst the hæmorrhoids are in a state of active inflammation. Sometimes, as I have before stated, the constriction of the sphincter produces sloughing, and a spontaneous cure takes place; if this is occurring, the process must be expedited by the liberal use of warm bathing and poulticing, and pain must be conquered by the administration of opium.

By the adoption and right application of these remedial measures, a large proportion of cases of internal hæmorrhoids may be cured, or relieved to so great a degree as to prevent annoyance; but many of the cases which come under the notice of the surgeon have existed so long, have reached such a size, and are productive of such troublesome and even serious symptoms, that some active surgical interference is required, in order to bring about a cure or render efficient relief. Originally the usual remedy in aggravated cases was the excision of the diseased part, and it was a remedy accompanied with little pain or difficulty; but the danger of hæmorrhage proved to be so great, that after the sacrifice of several lives the practice was abandoned. It is necessary, even when the excision of external piles is being performed, to take care that the mucous membrane is not too freely clipped, otherwise dangerous bleeding may result. I saw a gentleman nearly lose his life from the inclusion of a portion of mucous membrane in the blades of the scissors during an operation for external hæmorrhoids. The operation was done at 2 P.M.; and at 6 1 was sent for, and found that he had been bleeding profusely.

Until within the last few years the radical cure of internal hæmorrhoids was

effected by strangulating the tumour or tumours by means of one or more ligatures so tightly applied that in the course of a period extending from five to ten days the tumours sloughed, and together with the ligatures separated from the bowel. Indeed even now amongst the senior members of the profession this operation is practised, and there cannot be a doubt that, in the absence of a less severe method of treatment, that by the ligature was the best that could be desired, for it was unaccompanied with the dangers which attended upon the operation of removing internal hæmorrhoids with the knife or scissors, and was much more efficacious than the plan of treatment by strong nitric acid.

The operation by the ligature is practised in two ways. In the first method, the patient having been previously prepared by the exhibition of an injection in order to get the parts protruded, the tumours are seized separately by a vulsellum and brought down; the surgeon transfixes the base of each with a stout needle set in a handle and armed with a double thread; this is divided, and the tumour is tightly strangulated on each side, the threads are cut short off and the protruded parts are returned.

A modification of this plan consists in making a free incision by means of scissors at the base or inferior border of the tumour, and then a stout thread is looped around the pile thus bared of most of its surrounding tissue, and is tightly tied. In this operation there is no necessity to use a needle, and of the two operations, should the ligature be employed at all, it is undoubtedly the simplest.

The patient must keep his bed for some days after the operation. A full dose of opium should be given the first night, so that pain may be prevented and the bowels be confined; if there be much pain about the seat of operation, ice applied in a bladder continuously will give great relief. Retention of urine is apt to follow this operation, and when present must be relieved by the catheter. It is desirable to keep the bowels quiet for three or four days, if possible, and then to obtain an evacuation by a dose of castor-oil. Very likely the ligatures will separate on the first action of the bowels; at all events they generally come away on the fifth or sixth day. Some pain is felt in the part for a few days afterwards, and during this time the patient should keep quiet; convalescence may be expected in a fortnight from the time of the operation.

This is the general course of things when the operation is successful and unattended with any evil results of any kind; but it is well known that the use of the ligature is occasionally followed by very serious results: and, indeed, several instances have been made public where death has ensued after this operation, the cause of death being effusion on the brain, tetanus, and pyæmia, the latter disorder most frequently. Several fatal cases have occurred in the practice of my own personal friends, and I have had the misfortune to lose two patients after the use of the ligature. One of these patients was a gentleman in the prime of life and very fair health, who died with well-marked symptoms of pyæmia; and in the other case the fatal event was due to the loss of blood during and after the operation.

But besides the risk of death from some of these causes after this operation, it is known that other serious results occasionally follow and give much trouble.

A circumstance which occasionally obtains after the use of the ligature, and which causes great annoyance, is the existence of long-continuing and painful ulceration at the seat of one or more of the ligatures, for a period varying from weeks to months. Everyone who has had much to do with this operation must have met with such cases. These ulcerations are most difficult to heal, and give great annoyance both to patients and surgeons.

To sum up briefly, then, it may be stated with truth that there are the following objections to the use of the ligature:—The supervention of more or less pain; a tedious convalescence; occasionally death from pyæmia, tetanus, or general constitutional disturbances, and long-continued and painful ulceration at the seat of ligature.

It is the duty of the surgeon to adopt some other means, if he has them in his power, by which these results may be obviated, and by which the disease can be cured; and fortunately he is enabled to effect this by employing a mode of operation which is now being pretty extensively used, and which is well known under the name of the

operation by the clamp and cautery, and which I will now proceed to speak of; but before describing that modification of the operation which was introduced to the profession by myself, I must briefly refer to the history of this mode of treatment, which probably will almost entirely supersede the employment of the ligature.

As far as I am aware, this plan of treating hæmorrhoidal tumours was originally practised by the late Mr. Cusack of Dublin; but its introduction to London surgery is, I believe, due to Mr. Henry Lee, who so long since as 1848 described a pair of forceps or clamp, which he appears to have used extensively; for in his volume of 'Pathological and Surgical Essays,' published in 1854, he has narrated many cases where he employed it, and applied either nitric acid or the actual cautery for the purpose of arresting the hæmorrhage after excising the tumours. In addition to the clamp originally used by Mr. Lee, and which was somewhat cumbersome, there was another kind of instrument, shaped somewhat like a pair of scissors, and which was much more suited for the purpose.

In the year 1863 I first began to treat cases of internal hæmorrhoids and prolapsus by the clamp, employing, after excision, the strongest nitric acid for the purpose of obviating bleeding. I soon became convinced of the value of this mode of treating these disorders, but in a short time I found out that very great improvements in the construction of the clamp were called for, and, with the assistance of the late Mr. Matthews of Portugal Street, I introduced to the notice of the profession the instrument which bears my name and which is now generally used. It is shaped somewhat like the ordinary clamp used by Mr. Curling for the purpose of seizing and applying nitric acid to hæmorrhoidal tumours but the blades are so constructed that they

116 171.—Clamp.

meet accurately at their edges, and are closely fitted into one another by means of a raised surface on one and a groove on the other edge. In this way, and if the blades are made perfectly parallel, the most accurate compression is made upon a tumour or portion of mucous membrane. A more important feature, however, in the mechanism of this instrument is the adaptation of a light yet powerful screw to the shank of the instrument, just above the handles. The object of this is twofold—in the first place to compress the blades, and in the next to take off the compression after the actual cautery has been applied; and by the slightest turn of the screw, this may be effected so gradually, and yet so thoroughly, that should any vessel be left uncauterised, its situation can be at once seen by the issue or jet of blood, and the cautery can be reapplied.

The latest, and a very important addition to the instrument, consists in the adaptation of a layer of ivory to the outer surfaces and external edges of the clamp, so that the heat from the cautery cannot be transmitted to the surrounding parts, and thus much suffering is prevented.

I will now proceed to describe the mode of application of this instrument, and this description will apply both to cases of hæmorrhoids and prolapsus of the rectum.

In the first place, the part to be operated upon is made to descend either by means of an enema or by the patient sitting over hot water: the tumour is then seized by a pair of hooked forceps, and firmly held by an assistant. The clamp is now carefully applied to the base of the tumour, and the blades are closed by means of the

screw. After having seen that this is done effectually, the surgeon takes a sharp pair of scissors and cuts off the whole of the tumour; the cut surface is wiped, and carefully and repeatedly touched by the heated iron until it is considered that the entire surface is thoroughly cauterised.

The screw is now gently turned, the grasp of the clamp is thereby somewhat relaxed, and if any vessel has not been sealed up it will emit blood, and the cautery can be again applied. Sometimes this process may be needful two or three times before the bleeding is quite stopped. As soon as it is ascertained that the surface has been thoroughly cauterised, the clamp is removed, and if more than one tumour exists, each of them is successively dealt with in a similar manner. The finger, oiled, is then introduced as far up as possible into the bowel, so as to push the parts well up and cause the sphincter to contract; a suppository of two grains of extract of opium is introduced, and the operation is completed. If only one tumour requires removal, the proceeding may be finished in a minute or two; but if there are several tumours, the operation cannot be safely or satisfactorily concluded under ten or fifteen minutes.

Since the issue of the last edition I have made an important modification of this

FIG. 172.—Cauteries.

operation, consisting in the removal of the tumours by the heated cautery instead of the employment of scissors. The cautery is so constructed that its blade may be set either at a right angle to the shaft or parallel with it, and may form a triangle or half-moon, and its edge is serrated. When the tumour is embraced by the clamp it is seized by a blunt vulsellum and drawn forward; the cauterising iron is then applied at a dull red heat, and made to travel along the upper surface of the clamp steadily and slowly. By this means the tumour is removed, and of course every vessel is cauterised in this process. And thus the surgeon possesses a more

thorough means of preventing hæmorrhage. I have now almost entirely discarded the use of scissors.

For the purpose of locking up the bowels, the same precautions as are needful in other operations on the rectum are taken. At the end of the third or fourth day a dose of castor oil is given and the bowels are generally easily moved; a little blood which has collected in the bowel either during or after the operation may come away. If the patient has not been much weakened by long continued hæmorrhages, he or she may be allowed to get up; and in by far the majority of cases they do so; but if the health has been much shaken, or the operation has been extensive and has involved the removal of much skin, it will be advisable to keep the patient in bed or on the sofa until the bowels have been acted upon a second time, two days afterwards, when it will be found that the patient is able to move about or attend to his ordinary business.

I have now performed this operation in many hundreds of cases, and I can with truth state that, if it be properly done, there is hardly an element of danger in it. I have operated at all ages, from puberty up to eighty, and in instances of the utmost severity, in cases where the tumours have been immense, and when the patients have been so thoroughly blanched by long-continued bleeding that one would not dare to perform any operation unless convinced of its safety.

This operation is, I believe, particularly adapted for those cases of severe hæmorrhoids or prolapsus where, either from age or from the presence of some other concomitant disease, the operation by the ligature would of necessity be attended with danger. Thus in two instances of severe hæmorrhoids, attended by symptoms of paralysis, where the local disease produced much annoyance, I did not hesitate to use

the clamp, although in each case the patients were advanced in life; and the operations were attended with as little disturbance as in perfectly healthy individuals.

The advantages which I claim for this proceeding, which I now always adopt in cases of hæmorrhoids or prolapsus, are, that there is considerably less risk to life than when the ligature is used; that in the majority of cases the suffering both attending and following the operation is much less, and that the period of convalescence is rendered much shorter. It is true that the operation itself is complicated and somewhat tedious, as compared with that by the ligature, but these considerations ought not to weigh with the surgeon when the advantages of any particular proceeding are great and palpable.

A method by crushing has been introduced by Mr. Pollock and Mr. Benham. The operation consists in using a clamp which is applied to the base of the pile after being drawn down, and the blades are firmly closed by a screw. The pile is then removed by a pair of scissors, and the clamp is retained for two minutes. If any vessel bleeds on the release of the clamp a ligature must be applied. Mr. Coates of Salisbury has recently used a method consisting of their removal by cutting so as to get speedy union of the wound. A clamp is applied to the pile, catgut ligatures are passed through the base of the pile behind the clamp; the tumour is removed by cutting, and, the clamp being released, the sutures are drawn together; any vessel which bleeds being previously tied.

Nitric acid was strongly recommended by the late Dr. Houston of Dublin as a means of getting rid of some forms of internal hæmorrhoids. I have been in the habit of using it in certain cases of hæmorrhoidal affections for many years. Mr. Henry Lee has incorporated with his Surgical and Pathological Essays an admirable paper on this subject, and has spoken highly of the plan of treatment which I am now about to consider.

I have stated, whilst describing the nature of internal hæmorrhoidal diseases, that the condition in which they are found varies. I have endeavoured to point out those cases to which an operation is applicable, and have stated that this practice is justifiable in those instances where the tumours are large, mainly composed of tissue, in which the veins predominate, and have become indurated.

There are, however, other instances where the hæmorrhoidal tumours are small or moderate in size, and where they are evidently composed of morbid texture in which the small arteries rather than the veins are interested, as shown by their bright florid aspect, and by their tendency to pour out arterial blood whenever the patient is at the closet, or when the tumours are handled. These tumours are sessile, and generally not very prominent. They produce exceeding annoyance, and indeed prove most destructive to the health, as they generally yield a great deal of blood. Now, in such cases, an operation will undoubtedly be as effective as in the other instances before described; but this proceeding is not necessary, as the local use of the nitric acid is so eminently suited to them. The relief which one single application of the acid gives in these cases is remarkable; and an excellent cure may be effected if the whole of the diseased texture be subjected to its action.

About this particular kind of case there is no doubt in the mind of any surgeon who has seen the nitric acid applied in a proper manner. There is, however, a mixed class of cases where the remedy is an uncertain one, but in which nevertheless the surgeon is justified in trying it, and where I sometimes have succeeded when I little expected it. I refer to those cases where there is a hæmorrhoidal mass, consisting perhaps of one tumour mainly composed of venous ramifications and of a bluish colour, with one or more presenting the characters of the florid sessile pile; or one portion of the tumour or tumours may present the dark blue appearance and thickened membrane, and another portion of it may be brightly vascular, and have its mucous covering granular or slightly ulcerated. In this kind of mixed case I do not hesitate to try the acid, if the patient is particularly desirous; but I make a point of stating that it is impossible to depend upon any curative action in such a case, although in some instances the remedy has acted most efficiently.

To apply the agent in those cases where the tumours are large and indurated,

and have a deep blue colour, would be perfectly useless, and only bring discredit upon the nitric acid as a means of cure in other kinds of hæmorrhoidal diseases.

It is, however, in that class of cases not unfrequently met with, where there is not so much any decided hæmorrhoidal tumour, but where there is a congested and relaxed condition of the mucous membrane of the rectum, attended with bleeding to a greater or less extent, that the nitric acid acts so beneficially. Dr. Houston has compared this condition of the rectum not inaptly to that of the thickened conjunctiva after long-continued ophthalmia. The application of the acid to the diseased points from which the bleeding proceeds will soon remedy all the bad symptoms.

The following is the mode of applying nitric acid:—The bowels having been well evacuated some hours previously, the diseased portion to which the application is going to be made should be well exposed by making the patient sit over hot water for some few minutes; or if this is not sufficient, an enema of water should be thrown up the rectum, and the hæmorrhoidal disease will be brought well into view. The part to which the acid is to be applied should then be carefully wiped with a piece of lint. The surgeon then dips the extremity of a small flat piece of wood into the nitric acid, and touches the diseased surface carefully with it. The part touched, and the neighbouring mucous membrane, is well smeared with oil, and the whole is returned within the orifice.

It is not necessary to confine patients to their bed after the acid has been applied; and this is one of the reasons why the remedy is so desirable, many patients having neither the time nor inclination to submit to an operation which may keep them from their business or pleasures for a fortnight or more.

Within the last few years some French surgeons, and especially M. Chassaignac, have strongly recommended the employment of the *écraseur* for the removal of internal hæmorrhoids. The practice has also, to some extent, been followed by surgeons in this country. The object sought by the use of this instrument is the more or less rapid removal of the tumours without hæmorrhage. That this can be effected in a great number of instances there is not a doubt; and if no evil result were likely to follow, this practice would in all probability be adopted in many of those cases where an operation was required, notwithstanding that there is a great deal of pain attendant upon the process. One very serious consequence, however, of this plan of treatment has been met with in several instances in Paris: this is the occurrence of stricture of the rectum some time after the wound has become cicatrised. This very grave objection to the employment of the *écraseur* is sufficient to counterbalance its real or supposed advantages; and although it would not be wise entirely to discard its use, the necessity for it must be rare, and in those few instances where it would be required, the surgeon would do well to take every precaution to avoid the occurrence of contraction of the gut.

PROLAPSUS OF THE RECTUM.

During the time that the rectum is evacuating its contents in a natural and normal manner, more or less extrusion of the bowel occurs; but this is only momentary, for as soon as the action is finished, the mucous membrane is immediately withdrawn within the anal orifice, and no inconvenience results. When, however, from some particular cause, there is any impediment to its return, those changes, which ultimately lead to the disease we are considering, occur; the mucous membrane becomes congested and swollen; its attachment to the muscular tissue, naturally loose, becomes weakened; and in course of time the protrusion of the membrane becomes habitual, constituting one form of prolapsus of the rectum, and that the most frequent. In other cases, however, there is a protrusion not only of the mucous and submucous tissues, but of the whole of the thickness of the lower part of the bowel as well. A preparation in the Museum of King's College puts an end to all doubt on this point. This kind of prolapsus occurs not unfrequently in children, and is of great extent, the protruded bowel being sometimes five or six inches in length. In very old people, this complete prolapsus of the rectum occurs,

reaching to an immense size. On examining a recent case of prolapsus of the rectum, where the least amount of change has taken place in the structure of the parts, as for instance in a child, the protruded part is found to form a tumour of an oblong shape and cylindrical form, presenting externally the smooth vascular surface of the mucous membrane, which is generally of a more or less bright red colour, and covered with mucus; at the extremity of the tumour is the orifice or cavity of the bowel, and at the anus there is no deep furrow between it and the protruded part, as there is in the intussusception of the rectum. Even in the adult, when the prolapse is large and of recent occurrence, this mucous membrane may be as un-

FIG 173 —Prolapsus in Child.

changed in appearance and texture as when it occurs in the child, but the tumour has more of a globular form.

The most frequent condition in which a prolapsus of the rectum is seen is where there are one or two lateral folds of the membrane, varying from one to two inches in length, protruded from the anus, or one unbroken ring of protruded membrane is seen - but this is more rare. If the disease has not long existed, the membrane is not much changed in appearance, being only somewhat thickened and more vascular than natural, but should the bowel have been habitually prolapsed for some years,

FIG 174 —Prolapsus in Adult

considerable changes take place, and on examining an old case, the following will be the appearances. Externally, there will be a ring of thickened integument; within this the flaps of mucous membrane hang down, their lower portions being much thickened, having lost the peculiar character of mucous membrane, and being assimilated to integument; this change has taken place because the most dependent portion is that which either habitually remains protruded altogether, or is protruded for a longer time, and more exposed. On separating the flaps of the prolapsus, the upper part of the membrane is found either but little altered from its natural character, being red, smooth, and vascular, or superficial ulceration may have taken

place where the two portions have been in contact. There is more or less mucous discharge produced, but in pure prolapsus there is little hæmorrhage.

Sometimes, in persons advanced in life, the protruded part consists of a tumour as big as the fist, which has habitually protruded for a long time. In such a case, a very large proportion of the tumour consists of membrane more like leather than the natural tissue. In these old-standing cases, the sphincter becomes extremely relaxed, and the anus very capacious; there is generally a redundancy of loose and thickened skin around; sometimes it hangs down in long pendulous flaps—this state of the parts adds materially to the facility of the occurrence of the prolapsus.

In many cases the prolapsus of the rectum is complicated with distinct hæmorrhoidal tumours, which in fact are mainly, if not entirely, the originators of the affection; for when one or more internal tumours exist, they themselves, each time the bowels act, become protruded, and drag portions of the mucous membrane down with them; so that not unfrequently a patient presents himself with one or more folds of prolapsed membrane, and at the same time with distinct hæmorrhoidal tumours.

The inconvenience and suffering which prolapsus causes is considerable, for although at the onset of the affection the protruded part may pretty readily return within the sphincter after an evacuation, as time wears on it becomes necessary for the patient himself to return the part, which not rarely is a task of difficulty, and attended with pain; moreover, from the contiguity of the rectum to the neck of the bladder and urethra, there is often great distress of these parts—constant irritability, and even retention of urine, being an accompaniment of the affection; pain and uneasiness is felt in the loins and down the thighs; the intestinal canal and stomach also sympathise, the patient being troubled with flatulence, loss of appetite, and low spirits.

If the prolapsus cannot be returned by the patient, most violent symptoms occur—extreme pain in the part, and retention of urine; and if unsuccessful attempts are made to reduce the swelling, which is in all probability tightly constricted by the sphincter, violent inflammation of the part, attended with severe constitutional suffering, occurs; and in some instances sloughing of the protruded bowel takes place, by which means a cure is brought about, but the mischief may be such as to cause death. In cases where a prolapsus occurs in children to a great extent, and has been allowed to remain down for two or three days, the local and constitutional changes are not so severe; the prolapsed membrane, however, becomes exceedingly congested.

The causes of prolapsus are constitutional and local; thus, the disease is very frequently met with in individuals who have suffered from general debility and laxity of fibre. In children especially the affection is met with in instances where the health has been much reduced by insufficient nutriment, bad air, and want of proper attention. An adult or old person who suffers much from prolapsus usually has a weak pulse, a flabby tongue, and impaired digestion; and in the child there is an unhealthy and dry skin, a foul tongue, and a tumid belly. The local causes which produce falling of the bowel in children are stone in the bladder, and ascarides. In adults, constipation, sedentary occupation, the straining caused by stricture of the urethra, and enlargement of the prostate, are fertile causes of the disease. There is no doubt, moreover, that the pernicious plan of frequently using copious enemata is very constantly productive of the disorder.

In considering the treatment of prolapsus of the rectum, we shall first refer to that which is necessary in removing the affection as it is met with in young children. In the first place, it is necessary to seek for its cause; and especial inquiry should be made with reference to the urinary apparatus, for it not unfrequently happens that it is the irritation of a calculus in the bladder which produces the extrusion of the gut; and if this be so, it is obvious that the remedy consists in the removal of the stone. If there be not stone in the bladder, a collection of ascarides in the rectum may originate the disease; and the destruction of these parasites by a few doses of scammony and calomel, together with the daily injection of a few ounces of strong infusion of quassia, will prevent the prolapsus.

In by far the larger proportion of cases occurring in children the general health

will be found at fault, and this must be attended to before the prolapsus can be got rid of. In the first place, it is necessary to return the protruded bowel; and this is sometimes a work of difficulty, because the child struggles violently and cries. The protruded bowel should be gently but firmly grasped by the right hand, well oiled; careful pressure, so as to empty the vessels, should be employed, until the whole is returned within the sphincter. When the protrusion has been large, however, and the child is very violent, the gut will soon fall again; and in this case the best plan to pursue is to place the child under the influence of chloroform, and the bowel will be readily returned. A pad and bandage should then be employed in order to secure the part, and the buttocks and thighs should be closely retained together by the application of strips of plaster. The secretions of the liver and bowels should be rendered healthy by the use of small doses of rhubarb and hydrarg. c. creta; the skin be kept in good order by the warm bath; the child should be carried about in the fresh air; the diet must be nutritious and in small volume; and the strength and appetite are to be increased by small doses of the pulvis cinchonæ and soda. As the health improves, the prolapsus will cease to appear; but should this persist, the part may be bathed with a solution of sulphate of iron, gr. j. to ʒj of water; or an injection of tincture of sesquichloride of iron, ʒj. to ʒvj. of water, may be thrown up every morning after the evacuation of the bowels, and after the protrusion has been returned. In some cases the prolapsus will recur whenever the child evacuates. This accident, however, may be prevented by so managing that the child should be in a kneeling posture during the act. Another plan which sometimes succeeds in preventing the protrusion consists in an attendant drawing on one side the skin of the anus with some force during the time the bowel is being emptied; by this means a certain amount of temporary contraction is produced which prevents the descent of the gut. In adults, a considerable number of the cases which are not severe, and which have not been of long standing, may be cured by careful attention to the removal of those causes which have produced the disorder. Thus, if it has resulted from violent straining and constipation of the bowels, some mild aperient should be exhibited occasionally, which will prevent accumulation in the bowel, and render the contents more fluid. The compound rhubarb pill at night will have this effect; or, what is perhaps better, one or two teaspoonfuls of confection of senna should be taken. The patient should not eat largely, and should especially avoid vegetables in any quantity. He should take exercise, and be careful to use plenty of cold water to the parts after the action of the bowels. Occasionally a little cold water, or a few ounces of the decoction of oak bark, may be thrown up the rectum; and if there be the least protrusion left after the evacuation of the bowels, the gut, having first been well sponged, should be carefully returned.

By attention to these various measures, a prolapsus of small extent may either be entirely cured, or be prevented from increasing or proving troublesome. And therefore it is of the highest importance to place reliance upon medical treatment in such cases. In by far the majority of cases, however, which are presented to the notice of the surgeon, the prolapsus is either very large, or has existed so long a time that medical treatment would be of no use whatever. And then some strictly surgical means must be adopted, if a cure, or even if palliation of the disease, is looked for. If the case is of only recent occurrence, and yet the prolapsus be very voluminous and incapable of being returned, thereby causing much alarm and suffering, it is the duty of the surgeon at once to reduce the prolapsed bowel. This is best effected by placing the patient on his side, with his knees drawn up, and grasping the tumour either with the naked hand well oiled, or with a cloth intervening. Firm and steady compression should be used, until the whole of the tumour be returned within the sphincter. The patient should then lie quiet for some hours, and afterwards a pad should be applied to the anus, and be secured by a firm bandage across the perineum and around the loins. In order to prevent a return of the prolapsus, the whole or greater portion of the mucous membrane should be smeared over with solid nitrate of silver, or even with strong nitric acid, previous to its being returned by the surgeon. In one remarkable case of immense size occurring in a young man, I adopted this plan, with

the result of obviating the necessity of a bandage, which he continually had worn before.

In order to bring about an effectual cure of the chronic and severe cases of prolapsus, more decided means must be adopted. We have seen that the disease essentially consists in a relaxed and thickened condition of the mucous membrane, and a separation, as it were, of this from the muscular coat. When this is involved also, there ensues a weakness and detachment of the whole of the thickness of the bowel from the surrounding supports. The object to be obtained is to reduce the redundancy or relaxation of the mucous membrane, to promote adhesion between the several tissues composing the bowel, and to brace up the anus and the sphincter. The late Mr. Hey of Leeds was the first to propose a proceeding which ensured the latter result; and this consisted in removing the loose and pendulous flaps of skin which existed around the margin of the anus, in the case alluded to by him in his 'Practical Observations on Surgery,' p. 443. In some cases, where the sphincter is very relaxed, and the flaps of integument loose and thick, a cure may be brought about by the removal of these alone; but when the prolapsus is very large, and a considerable portion of the mucous membrane has become converted into tissue approaching to integument, it will be necessary to adopt the modification of the operation proposed by Dupuytren, which consists in removing radiating folds not only of the skin at the margin of the anus, but also portions of the diseased mucous membrane. This operation is effected by laying hold of the fold of skin on each side of the anus with forceps, then with a sharp curved pair of scissors removing both skin and mucous membrane. In very severe cases four or six applications of the scissors may be necessary. The operation is soon accomplished; as the wounds heal, contraction takes place, the aperture of the anus becomes diminished and braced up, and the prolapsus no longer occurs.

It is important to bear in mind that, in very severe cases, not only is it necessary to remove the relaxed integument, but portions of the mucous membrane, which in instances of long standing has become converted into a tissue more like leather than anything else, must also be taken away. If this step be not resorted to, a disappointment will ensue as regards a complete remedy of the prolapsus. Hence the surgeon must think of the possibility of somewhat severe hæmorrhage, which will occasionally occur. After a portion of the mucous membrane, however small, has been snipped away, I have seen it occur to a very great extent, and when it was least expected.

If hæmorrhage to a large extent does occur after a surgical operation on the rectum, the patient will in a few hours complain of tenesmus, and express a desire to go to the closet; he will then evacuate a large quantity of blood and become faint. In such a case it will be necessary to clear away any coagula which may be in the gut, to elevate the pelvis, and introduce some ice into the bowel. Should this not stop the bleeding, a careful examination should be made with a speculum, and the bleeding orifice be looked for and tied, or, if at hand, the hot iron should be freely applied. Sometimes it will be difficult, or almost impossible, to effect this; and then the rectum must be carefully plugged by portions of sponge or lint, to which a thread should be tied, that the compress may be more readily withdrawn when the bleeding has ceased.

It may here be stated, that the risk of severe hæmorrhage after the mucous membrane has been excised may be in a great measure obviated by the surgeon taking care to introduce, through the edges of each incision, one or more fine sutures before the patient is left.

Another mode of curing prolapsus consists in the application of the ligature to portions of the prolapsed membrane. This plan is especially adapted to those cases where there is great laxity of the mucous membrane, and where the surrounding integument is not much involved; also to those cases where the prolapsus is associated with one or more hæmorrhoidal tumours. This operation was originally proposed for prolapsus by the late Mr. Copeland, who found it to answer his expectations most admirably. It is easily done, by pinching up, with a pair of forceps, 11

portions of the diseased membrane, applying around each a tight thread, cutting off the extremities, and returning the parts within the sphincter. If there are distinct hæmorrhoidal tumours to deal with, the operation as undertaken for them, and described in another place, must be performed. As the prolapsus is in a great measure the result of the hæmorrhoids, the cure of the latter will be followed by the disappearance of the former. In some cases of prolapsus where the mucous membrane is not altered in its texture, strong nitric acid is used with great benefit.

Cases of prolapsus are occasionally met with in persons of very advanced age, or who are suffering from some internal disorder which would forbid the employment of the ligature. Probably there is, in conjunction with an extensive prolapse of the mucous membrane, a very weakened condition of the sphincter, and an abundance of loose and thickened integument around the anal orifice; consequently the use of nitric acid alone will not suffice to remedy the disorder, even if the mucous membrane be not much altered in its character. In such cases I combine the use of the nitric acid with the removal of two, three, or four slips of the thickened integument from around the margin of the anus. The acid should first be thoroughly applied to the mucous membrane on one or more occasions; and after the lapse of a few days the subsequent part of the treatment should be adopted by using the scissors in the manner before described. Most beneficial results will follow from this practice, and it may be undertaken without fear of danger in cases where the ligature would not be justifiable.

Although either of these methods of treatment may be adopted with success, I now almost invariably remove a prolapsus in the adult by the operation with the clamp and cautery, as in instances of hæmorrhoids, and in precisely the same manner. If the tumour be small, it is only necessary to remove one or two folds of mucous membrane; but if, as in some cases, it be very voluminous, it is needful to apply the clamp to several portions of the protruded membrane. If there be great laxity of the anus with redundancy of skin, two or three slips of the latter should be removed with the scissors, as in the operation of Dupuytren. I find this treatment is just as successful as when it is practised for the removal of hæmorrhoids.

In those cases where any operative measure is not advisable, great relief may be obtained by the use of a pessary or spring pad.

FISTULA IN ANO.

The artificial communication between the cavity of the rectum and the neighbouring textures denominated fistula in ano constitutes an affection of very great interest and importance, as there is a difference of opinion regarding the exact pathology; and for the most part an operation more or less severe is required for the cure of the disease.

Very opposite opinions have been propagated by eminent surgeons regarding the formation of fistula. Thus, it has been confidently asserted by Sir B. Brodie that the origin of the disease was the existence of an ulcer in the mucous membrane, and that the suppuration in the neighbouring textures was subsequent to and dependent upon this ulceration. On the other hand, it has been as confidently stated by Mr. Syme that the first step in the formation of this disease was an inflammation and suppuration in the cellular tissue external to the bowel, and that the abscess subsequently opened into the gut, and thus the fistula was constituted.

There can be no doubt that the disease originates in both ways. We are acquainted with the fact that inflammation and ulceration of the mucous coat of the rectum occur both spontaneously and as the result of injury produced by foreign bodies; ulceration having occurred, some of the contents of the rectum escape into the surrounding cellular tissue, and excite suppuration.

A fistula is sometimes produced by direct violence; an illustration of this occurred recently in my practice. A gentleman had a bougie roughly thrust up his anus; this penetrated the coats of the bowel, suppuration took place in the tissues around. I saw him seven weeks after the accident, and found an opening in the bowel the size

of a sixpence leading to the cavity; there was no external opening. In the operation I made an incision in the skin and laid open the parts included, and the fistula was soon cured.

In the majority of cases of fistula in ano, the first step in the formation of the disease is the existence of an abscess in the cellular tissue surrounding the bowel; as the matter increases, the various textures are involved, the cavity of the bowel is pressed upon, the mucous and muscular coats are separated to a greater or less extent, and at last the former membrane is penetrated.

The external opening may present itself as a simple minute puncture, and when situated close to the anus may be so hidden between the folds of the integument as readily to escape observation, unless it be carefully looked for; the only thing which marks its presence being a slight moisture escaping from one point when pressure is made. In other instances of more extensive and old-standing disease, the opening or openings present themselves as somewhat prominent apertures, not unlike those seen in connection with dead bone, and surrounded by more or less erythema of the skin, so that there is not the least difficulty in finding them.

Although for the most part it will be found that the external opening of a fistula is by the side of and some little distance from the anus, it is well to know the fact that sometimes it is so close to the circumference of the anus that it is necessary for the patient to protrude the parts well before this aperture can be discerned.

An external opening does not always exist, and then is constituted what the older surgeons named a blind or incomplete fistula. This form of the disease is somewhat rare, and it is very likely to be overlooked or misunderstood.

The internal opening of a fistula nearly always exists; and indeed, according to that view which looks upon the formation of the disease by preliminary ulceration of the mucous membrane, an opening must necessarily obtain; but there is no doubt that there are cases of incomplete fistula where there is no opening into the bowel; an examination on the living body alone might not be a sufficient proof of this, for the opening may exist, and not be ascertained; but no such source of deception can occur after death. There are three specimens in St. George's Hospital Museum, as well as two preparations in the Museum of St. Bartholomew's Hospital, which show this. On careful examination, however, it will be noticed that the mucous membrane of the rectum at the spot where the opening would have existed is very much thinned.

Formerly it was considered that the internal opening was situated much higher up than is really the case. Subsequent investigations, however, and especially those instituted by Salatiér, Ribes, and Velpeau, have proved that in the larger number of instances the internal opening is situated within an inch or an inch and a half from the anus. In more rare cases, however, it happens that the internal opening will exist as high up as three inches from the anus. It is rare that more than one inner opening exists; and it has been affirmed by a recent writer that it is always single; but this is an error, as cases are occasionally met with where there are two or more distinct apertures in the gut. And it is easy to understand how this occurs; for in some of the more severe cases of abscess near the rectum the matter strips up the gut, separating it from the cellular tissue to the extent of three or four inches; and it is but likely that the mucous membrane should become thinned, and ultimately perforated, by the pressure of the matter at more points than one.

The course which the sinus takes differs; it may be simply subcutaneous. Very frequently it runs through the fibres of the external sphincter, or it may be found to traverse the substance of the levator ani. In one very beautiful preparation in St. George's Hospital Museum the fistulous canal is shown to be running closely beneath the fibres of the internal sphincter.

Sometimes the result of extensive suppuration around the lower part of the rectum is the formation of a double fistula, either complete or incomplete; that is to say, there may be a fistulous tract on either side, having an internal as well as an external aperture; or a sinus may exist on either side of the bowel, and yet there be only an opening into the latter on one aspect; or there are two sinuses, one of them

opening both into the bowel and on the skin, whilst the other has only an internal aperture. There is occasionally also a curious condition, where the fistulous sinuses surround the back part of the rectum, and have a common opening in the bowel; this form of the disease has been not inaptly called the *horse-shoe* fistula. In very severe cases the sinuses are found to be branching out across the buttock in various directions; this state is not uncommonly associated with stricture of the bowel of either a simple or malignant character. In an instance which I saw in consultation with Mr. Holberton of Hampton, the sinus extended so far down as the lower third of the thigh posteriorly. The fistula in this case was the result of stricture one inch from the anus.

The causes which produce fistula are various, and, understanding its pathology, we must look to those circumstances which are liable to excite inflammation and suppuration about the rectum. In some rare cases the disease is of a traumatic origin. Thus a fish-bone may have adhered to the mucous membrane of the rectum, and produced ulceration and subsequent abscess, which has degenerated into fistula; or the ulceration may have primarily taken place in the mucous membrane in persons who have suffered from severe dysentery. In the greater number of cases, however, when abscess has been the primary step, the morbid action has been idiopathic, occurring in persons who have been out of health, or who have been ill from some specific disease. Those who have lived long in tropical climates, and who have suffered from disease of the liver, are doubtless more liable than others to get fistula. A violent blow upon the perineum or ischio-rectal region will produce abscess which will terminate in fistula. I have recently operated upon a very healthy young man where the disease could be traced to this source.

When an inner opening exists without any external aperture, the diagnosis is somewhat difficult. The patient will complain of having suffered from more or less pain about the rectum; this had gradually become more severe, until there was perhaps some alleviation, accompanied with a discharge of purulent matter from the anus. On examination, the surgeon will detect a distinct and circumscribed induration by the side of the anus, very painful to the touch; and on pressing the part towards the anus purulent fluid will be observed to escape in considerable quantity. And when the integument has become thinned, fluctuation may be discovered; but not in all cases.

It should not be taken for granted that, because a sinus exists close to the anus, it must be connected with the rectum; for abscess and fistulous openings may exist in connection with disease in other parts. Thus sometimes an ordinary pelvic abscess may discharge itself close to the anal aperture, or an abscess in communication with the hip-joint will open into the ischio-rectal fossa. An abundant discharge from a cavity connected with the prostate gland took place in this situation in a recent case under my own care. Necrosis of the tuberosity of the ischium or of the extremity of the sacrum may exist, and the aperture in connexion with the disease may be present in the same situation.

I attended an elderly gentleman some time since who had suffered for several years from a fistula. Two operations had been performed upon him by a most eminent surgeon, but the fistula remained unhealed. When he came under my observation a most careful examination was made with the view of detecting the cause of the failure of these operations; and by passing the probe up to the posterior part of the rectum, a portion of necrosed bone was felt. The fistula was freely incised, and a small piece of the sacrum was removed. The existence of this disease had been overlooked, and hence the failure of the two previous operations, which had been performed as for an ordinary fistula in ano. I may mention that after the third operation the patient perfectly recovered.

In order to bring about the cure of a fistula in ano, it is necessary in the great majority of cases to perform a surgical operation, which fortunately, from the attention devoted to this disease by Pott and others, is a much more simple business now than it was in former days, and if proper judgment be used in selecting the cases, is almost always attended with success.

Before, however, proceeding to consider more especially the treatment for the disease when the fistulous communication has been formed, it is necessary to make

some observations on the importance of dealing promptly with the inflammatory and suppurative process which forms the first stage of the affection. When a patient is suffering from the symptoms of threatened abscess near the rectum, he should lie in the recumbent posture, and the bowels should be thoroughly evacuated by a dose of calomel, followed by castor-oil; hot fomentations and poultices should be assiduously employed, and the diet must be sparing. By the early adoption of these measures threatened abscess will be arrested, and all the symptoms subside. If, however, there be good reason to believe that matter has already been formed, it will be necessary, in order to prevent a fistula, to make a free incision into the centre of this swelling with a narrow sharp bistoury. In some cases, where the pus is deeply seated, the point of the knife must be passed much farther than would at first appear to be necessary. In such a case the evacuation of the abscess will be facilitated by the introduction of the left forefinger into the gut; by its assistance the swelling may be pushed forwards and made more prominent. When the abscess has been opened, it will be prudent to insert a small portion of lint into the aperture, in order to prevent its closure. The part should then be well poulticed, and the patient should remain quiet during a few days.

In many cases, where the inflammation of the cellular tissue has not existed long, and where the general health is not much at fault, an abscess close to the rectum will completely heal by this prompt evacuation of its contents, and thus the fistula will be prevented. Hence is shown the vast importance of properly understanding the pathology of this disease, and thereby being able to arrest it in its first stage.

In those cases, however, where there has been extensive mischief, and the lower part of the rectum has been much denuded, or where the general health has been weakened from this or some other cause, even this prompt surgical treatment will not prevent the abscess from degenerating into a fistula; and in other very numerous cases, the abscess has been allowed to burst, and the fistulous communication between the gut and the external surface has been formed.

In some cases where the sinus is short and free from induration, it may be made to heal by the employment of irritating injections thrown into the canal. Those which are likely to prove of most service are injections composed of the pure tincture of cantharides, or of the tincture of iodine undiluted, which should be used daily. Another method of healing these fistulae consists in irritating the sinus by passing a silver probe covered at its extremity with fused nitrate of silver. Each of these measures is occasionally successful, especially when, at the same time, the general system is improved by medical treatment, and by change of air. Therefore, in those cases where there is no cause for hurry, or where the patient is unwilling to undergo an operation, these means of cure should be tried perseveringly, and both patient and surgeon will sometimes be rewarded with success.

Fistula in ano may be treated successfully by ligature, and it is a method which was warmly recommended by Mr. Luke. The operation is effected by passing a common ligature, by means of an eyed probe, through the external aperture into the bowel; then adapting the two ends of the thread to a small screw, which can be tightened from time to time as the ligature is cutting its way out from the fistula. The process of separation is generally completed in a week or ten days; and as the ligature ulcerates away, the cavity behind becomes gradually filled up. The mode adopted and the instruments used by Mr. Luke are described in the '*Lancet*' for 1845, p. 221.

There are some advantages in the ligature. Thus, it may be employed without fear of producing hæmorrhage; and therefore in those rare instances where the inner opening of the fistula is situated high up, and where serious bleeding may be expected to arise after a cutting operation, this mode of treatment should be adopted. Again, there are patients every now and then to be met with who are so nervous about a cutting operation, that even with the promise of chloroform, they will not submit to the knife; in such the treatment by ligature can be advantageously substituted. It is not a method adapted to cases where the sinuses are very tortuous and extend in various directions; but in those instances where the fistula is simple, there is no doubt

that the application of the ligature will be followed by success, although the process is a somewhat tedious one, and sometimes it has to be abandoned in consequence of the pain and annoyance caused. The use of the elastic ligature has lately been advocated in the simpler forms of fistula by Mr. Allingham.

In by far the majority of cases of fistula in ano, an operation by the knife—that commonly denominated *the operation for fistula*—is needed, if a satisfactory and efficient cure be looked for. This consists in the division of the structures situated between the sinus and the cavity of the intestine, and, in fact, the laying open of the entire fistula from one orifice to the other. This proceeding is rendered necessary in many cases of obstinate sinuses situated in other parts of the body; and it is easy to understand how imperatively it is called for when a sinus implicates a part periodically acted upon by a powerful sphincter muscle, whose contractions alone will suffice to prevent the healing of the fistula, even were there no other causes at work to impede this process. The object, therefore, of the surgeon in performing the operation is not only to lay the sinus open, and thus place it in a more favourable condition to heal, but by dividing the sphincter muscle to paralyse its action for a time, and thus to keep the wound at rest—a proceeding found to be essential for a cure, not only here, but in the treatment of wounds, sores, or injuries in other parts of the body.

The operation, as performed now, is, in the majority of cases, a simple one, compared with the same before, or even after, the days of Pott, whose writings tended so powerfully to diffuse correct views regarding the pathology and treatment of fistula in ano. Instead of excising the fistulous tract, or even of making very free incisions high up in the gut, the surgeon only finds it needful to divide those structures which are limited by the two orifices of the sinus; and it is now pretty clearly ascertained that, in the majority of instances of the disorder, the inner opening is met with at a point not higher than an inch, or little more, from the anus; and it is not necessary to carry the incision higher into the rectum, even though the sinus may extend for some distance by the side of the bowel above the opening.

The operation is performed in the following simple manner:

The patient, who has had the bowels well cleared out previously both by castor-oil and by an enema, and who has been rendered insensible by chloroform, lies upon his side; an assistant separates the buttocks. The operator introduces his left forefinger, well oiled, into the rectum, and then passes a curved, narrow-bladed bistoury with a blunt point through the external opening, and carries it along the sinus until the point is made to enter the bowel through the internal opening, and to come in contact with the forefinger, the bulb of which is turned towards the orifice of the sinus. This being effected, the surgeon, by a kind of sawing motion with the hand holding the knife, and assisted by the left forefinger, pushing the instrument downwards, divides the whole of the structures between the sinus and the anus, bringing out both knife and forefinger together. In those cases where sinus is single, this one incision is alone necessary; but where there are one or more tracks branching off, the bistoury must be carried along them, so that the undermined integument may be fully opened and the wound made one.

If it has been ascertained that an internal opening does not exist, the knife must be forced through the mucous membrane into the cavity of the bowel at that spot where the tissue is found to be thinnest, and the operation should be then completed. It is not necessary to carry the knife to the very extremity of the sinus, if this extends to a considerable length, whether there be an inner aperture of the fistula or not.

After the operation is completed, a small strip of oiled lint should be placed lightly between the edges of the wound, but there should be no plugging or thrusting in of large pieces; a pad and bandage may then be lightly, yet firmly, placed over the parts; the patient should be kept quiet in bed, and should have a dose of chalk-mixture and laudanum, in order that the bowels may be confined; his diet should be such as not to cause much fecal accumulation. At the end of three days, a dose of castor-oil should be given; and after the bowels are evacuated, the wound should be

cleansed and dressed again. A small portion of lint should be introduced from day to day within the edges of the wound; and if it look flabby, a solution of sulphate of zinc or of copper may be employed by means of the lint. In the majority of cases, if there be nothing adverse, the wound made in the operation will heal up soundly in two or three weeks. In some cases, however, without any appreciable cause, the healing process will be retarded; a useful remedy in such a case is the confection of black pepper, in drachm doses, every night; or it may be needful to send the patient away for change of air, when the wound, which has hitherto become stationary, will often commence healing again rapidly.

Before undertaking the operation for fistula, the surgeon should take especial care to examine the patient, not only locally, but as to the general state of health; for this disease is not unfrequently complicated with other morbid states, which may either render any cutting operation unadvisable, or may induce delay in order that some preparatory measures may be adopted. Thus it is well known that fistula in ano is not unfrequently associated with pulmonary disease; and if this be found to exist, it certainly would not be prudent to perform the operation, unless the suffering from the local affection should be very great, and the mischief in the chest be very slight. If the fistula be cut when the patient is suffering from phthisis pulmonalis, the wound, in the majority of cases, will not heal up, even though life may be spared for a considerable time.

There are other cases, also, where fistula is met with in persons who have had their health broken down by a long residence in hot countries, and have suffered from dysentery and disease of the liver; or cases are seen where either the liver or kidneys have become structurally altered by free indulgence in ardent spirits. An operation in such instances is generally to be avoided, unless there be some urgent reason for its adoption.

When a fistula is connected with a stricture of the rectum, a careful consideration of the case is required. If the obstruction be of a malignant nature, of course any operation is not to be thought of. It may, however, be somewhat difficult to ascertain at the early stage of the affection whether the stricture be of a malignant character or otherwise, and the fistula in connection with it may have been divided. In this case, either this wound will not heal, or its cicatrix will put on a scirrhus character.

I was called to see a middle-aged woman, who had been operated upon on two occasions for fistula, unsuccessfully, by a surgeon of large experience. On examination I found that the wound had only partly healed, and had taken on a scirrhus character. On examining the rectum, I found that there was a firm indurated stricture about an inch up, and there was much hardness about the parts altogether. I gave an opinion at the time, that it was a question whether the disease was not of a malignant character, although the features were not decided. At any rate, the ill success attending the operations for the fistula was due to the existence of the disease, which perhaps at the time was overlooked. I ascertained from a medical friend that this woman died six months afterwards, and that the disease had manifested itself as cancer.

If a fistula be complicated by a simple stricture of the rectum, and this latter be overlooked, the operation will in all probability fail. When the stricture is recognised, preliminary treatment is to be employed before the knife is used. The contracted part should be dilated by the bougie, and subsequently the sinus is to be laid open; during the after treatment, too, this use of the bougie must be strictly adhered to, otherwise contraction will recur, and the sinus will not close. When the inner opening of the fistula is situated above the stricture, this latter may be divided at the same time that the sinus is laid open; but it is better even in such a case to employ the bougie prior to the operation, if there be not any decided objection to this proceeding.

Every now and then a weakness or entire loss of power of the sphincter occurs after its division, more especially in those instances where two or three operations have been rendered necessary. In three instances which have lately presented themselves to my notice the operation had been repeated thrice in two of the patients, and twice in the other. In two out of the three the loss of power was complete; when

it is but partial, recovery may take place after the parts are thoroughly and soundly cicatrised.

In some rare cases there will be an external opening on either side of the rectum, with only one inner aperture. It then becomes a question as to what should be done. The operation performed on that side where the inner opening exists, together with slightly enlarging the mouth of the sinus on the other, will sometimes suffice; but if this be found to be ineffectual, both the fistulous tracks must be freely incised. The objection to this double operation consists in the circumstance that loss of power over the sphincter may ensue. When there is a complete fistula on both sides, a double operation must be performed, and it should be effected on one occasion.

ULCER OF THE RECTUM AND ANUS.

Painful ulcer of the rectum, or fissure of the anus, is that where the ulceration is situated partly without and partly within the rectum. The existence of this form of ulcer is not unfrequently overlooked, because, although the symptoms are peculiar and striking, the pathological change causing them is not readily detected, unless by one accustomed to look for it. The patient who is suffering from this form of the affection will complain of having what he terms the piles; on questioning him closely, it will be ascertained that there is not any protrusion, but that he feels more or less acute pain in passing the contents of the bowels. This pain, instead of diminishing, increases in severity after the act, and lasts for a considerable time, varying from a quarter of an hour to four or five hours; it then ceases, and there is no suffering until the bowels are again moved, when repetition occurs; and as time goes on the symptoms become more severe. There is also in some cases a flow of blood, and in all a more or less purulent discharge. On examination there will be nothing visible externally, with the exception, perhaps, of a small excrescence or pile about the size of a currant; and this is found in a large proportion of cases of ulcer of the anus and rectum, and is a sign of great importance. On requesting the patient to protrude the parts as much as possible, and separating the sides of the anus very carefully, the ulcer will be seen situated at the base of the little tumour, which in nine cases out of ten is at the posterior border of the anus. In one case the ulcer may be only the eighth of an inch in length, and its extent may be defined by the eye alone; in another instance it may be more than half an inch in length, and, extending beyond the verge of the anus, implicate the mucous membrane of the rectum itself. When this is the case, the limit of the ulcer cannot be seen, but it is necessary to introduce the finger into the rectum, when the peculiar and roughened sensation caused by the breach of surface is readily detected by a practised hand. This introduction of the finger is accompanied generally with excessive pain.

It is extremely important to employ the greatest care in the investigation of these cases; for a small ulcer may be easily overlooked, in consequence of the rugæ around the anus enveloping the part and hiding it from sight. It is well, therefore, when this disease is suspected, to have a good light, and to take care that the examination be not made until the bowels have been well evacuated and the parts well cleansed. With regard to the pathology of this affection, it is difficult to come to any correct conclusion. There is good reason to believe that, in all or most cases of spasmodic constriction of the anus, a diligent search would bring to light some slight ulceration or excoriation, on which the symptoms depend. One of the most recent authors of repute, Mr. Quain, holds the view that the sphincter is but secondarily or sympathetically affected, and that the painful spasm is not a disease in itself.

I think, perhaps, that I have more frequently met with this affection in women than in men; and most certainly they are more liable to other morbid conditions which produce much the same kind of symptoms as those afforded by the painful ulcer. Amongst these I may mention the displacement of the womb, which pressing upon the rectum gives rise to a difficulty and pain in defæcation; that painful condition of the coccyx which is the result of an injury, produces also very similar symptoms. I saw recently a very marked case of this kind, where an eminent

physician-accoucheur considered that an ulcer of the rectum existed, whereas, on examination, no such lesion was found, and appropriate remedies applied over the coccyx soon brought about a removal of the symptoms complained of.

The treatment of this affection consists either in the employment of local agents, or in the use of the bistoury. In those cases where the ulceration is only of slight extent, is not carried far within the sphincter ani, may be comprehended by the naked eye, and the symptoms have not long existed, a cure may be brought about by careful attention to the bowels, by the employment of rigid cleanliness, and by an occasional application to the ulcerated spot of the solid nitrate of silver or sulphate of copper. After the sore has been touched once or twice, the effect will be, in those cases which are benefited by this treatment, a considerable mitigation of the severe pain which has troubled the patient when at the closet and afterwards; and the sore, instead of presenting the greyish appearance which is usually observed, puts on healthy granulations, and slowly contracts in size. In order to assist this process, a lotion of sulphate of copper or sulphate of zinc, one grain to an ounce of water, should be applied two or three times a day; or if these do not succeed, the ordinary black wash may be used with benefit. The daily introduction of a full-sized bougie, made of yax or of yellow soap, will sometimes act beneficially, by distending the sphincter and producing such an amount of irritation as will set up a healing process in the sore.

In the more severe cases, however, this local treatment will fail to produce a cure; and there are some persons who have been brought to such a state of suffering, local and general, that it will be unwise to trust to measures which either may not succeed, or which may be slow in giving relief. A modification of the operation which was originated by the French surgeon Boyer, and which consisted in the division of the sphincter and the tissues around, is now generally undertaken by the best surgeons, and is found to be successful in remedying this affection.

The operation itself is simple and easy of execution. The bowels having been well cleared out previously by a dose of castor oil or an injection, the surgeon should then take a straight narrow-bladed, *probe-pointed* knife, and having passed his left forefinger into the rectum beyond the extremity of the ulcer, he should introduce the point of the knife very carefully, and commencing his incision above the ulcer, carry the cutting edge fairly and quickly through the centre of the sore or fissure. It is absolutely necessary to include the whole length of the sore, and not to cut to one side; and therefore it is well that an assistant should open the orifice of the anus as far as possible, in order that a good view of the greater part of the ulcer should be obtained by the operator. There is very frequently a small external pile or thickened fold of integument at the base of the sore; this should also be removed, as well as any other pendulous flaps of skin which may encircle the anus. Scarcely any dressing is required after this operation; a small strip of lint dipped in oil may be introduced, and kept in for a day or two, but it is not necessary. It is as well to give an opiate after the operation: in the first place, to lessen pain; and secondly, to prevent the action of the bowels, which should not be allowed for two days or more; and then this action should be produced artificially by a dose of castor-oil. The wound should be daily dressed with a dossil of lint dipped in a weak solution of sulphate of zinc and water. This dressing is not absolutely necessary; but there are some cases in which the wound becomes sluggish, and then a slight stimulation is desirable. The use of the *confectio piperis nigri* will assist the healing of the wound after this operation, as after that for rectal fistula.

It is very necessary to make a careful examination of the rectum at the time of operating, for it is very possible that a polypoid growth will be found to exist in conjunction with and above the ulcer, and which may easily escape observation. I have quite accidentally discovered these growths more than once lately after I had completed this operation, and had introduced the finger high up into the bowel for the purpose of passing a suppository. If one or more of these growths were left behind, it is probable that the cure would not be complete, or at all events their presence might produce a return of the ulceration; for I believe that not unfrequently it is the presence of this polypoid growth that originates the fissure or ulcer.

It is necessary here to refer to a morbid condition which not unfrequently exists in combination with this painful ulcer, and which may be easily overlooked, viz., *internal fistula*. When this exists the small ulcer will in reality constitute the opening, and if a probe be introduced it will travel upwards, under the mucous membrane, for an inch or two, or it sometimes can be passed downwards towards the outlet under the external sphincter. In those cases, there is, in addition to the peculiar pain, a considerable amount of discharge—the existence of this should at once excite the attention of the surgeon. If a channel exists not only must the ulcer be divided, but the whole sinus is to be laid open. I have met with several cases where a neglect of this important step has rendered the whole operation a complete failure, and where, on laying open the sinus, a cure of all the symptoms has been effected.

It has lately been recommended in France that an operation effecting the same purpose as division of the ulcer should be performed. This consists in the forcible tearing open of the sphincter by the introduction of the two fingers into the anus, and using extension. There has been sufficient evidence placed before the profession to prove that this mode of dealing with fissure of the rectum is attended with success; but it is a proceeding so rude and unsurgical, that we trust the surgeons of this country will not forsake the simple and effectual means we have described when any operative measure is required.

STRICTURE OF THE RECTUM.

This disease consists essentially, in most cases, of an adventitious deposit thrown out upon or around the coats of the intestine. In the most simple form of stricture, there is a more prominent ring of apparently hypertrophied mucous membrane, either entirely or only partially surrounding the cavity of the gut. A careful examination on the living body with the finger, and an investigation of the diseased part after death, shows that the thickening is produced in the areolar tissue underneath the mucous membrane; although there are preparations to be met with which lead to the belief that the encroachment upon the cavity of the gut is caused merely by a prominent fold or ring of the mucous membrane itself. In the more marked cases of the disease, not only is the deposit found in the submucous cellular tissue, but there is a thickening of the muscular coat as well, produced, not by hypertrophy of this investment, but by an infiltration of the fibrous exudation through the meshes of the muscular texture. In the more severe cases, where the disease has lasted for a long period, this fibrous deposit becomes more extensive and dense. In most cases there is, together with a very narrow contraction, a large amount of thickening of the coats of the bowel; but every now and then a considerable amount of contraction is found without any, or with scarcely any, consolidation of the surrounding tissues. In one very interesting preparation in the Museum of St. Bartholomew's Hospital, there is a tight contraction of the gut about three inches from the anus, the cavity being diminished to about one-quarter of an inch in diameter for the extent of an inch; but there is not any thickening of the tissues whatever, and the contraction is supposed to be owing to muscular action. In some rare instances, the stricture is caused, not by any deposit in the walls of the gut, but by fibrous bands running across the cavity of the bowel; thus, in King's College Museum there is a curious specimen, which shows a stricture about one inch and a half from the anus, consisting of a cup-shaped septum, formed of thick bands running across, in which are three or four distinct openings which would each admit a small quill.

In a few instances, the fibrous deposit producing the thickening—which is the essential feature of the disease—involves only a portion of the circumference of the bowel, as was found in a case of stricture of the rectum lately brought to me for consultation. In by far the greater number, however, the whole circumference of the gut is implicated in the condensation which has taken place. It may be much more decided on one side than another.

The extent of bowel affected lengthwise also varies much. The disease may

involve only one or two lines of the gut ; much more frequently the deposit extends from half an inch to an inch and a half in length ; sometimes the consolidation implicates three or four inches of the intestine ; and, in rare cases, there is a general thickening of the tunics, involving nearly the whole of the rectum, and producing a considerable diminution in the cavity of the bowel.

The pathological changes which occur as the result of stricture of the rectum affect the bowel in the immediate locality and behind it ; important results are also witnessed in the tissues surrounding or in connection with the bowel.

The intestine immediately above the stricture is, in the majority of cases, more or less dilated ; in one instance the cavity being widened only to a small extent, whilst in another, where the stricture has been very tight and of long duration, the intestine is distended in a great degree ; thus in one specimen in the Museum of Guy's Hospital, the rectum is five inches in its diameter. There is also a thickening of its tunics above the part immediately diseased, in a great measure owing to an increase in the development of the muscular coat ; the law being followed here, that if there be any obstruction to the passage of the contents of a muscular organ, the increased energy necessary will be marked by an increase in the size and strength of the muscular fibres. The mucous membrane above the stricture is generally in a diseased condition, being either preternaturally vascular and thickened, or, in long-standing cases, superficially or deeply ulcerated, and sending forth a copious unhealthy discharge. Below the seat of stricture there is not much alteration of the parts ; the mucous membrane is, however, sometimes found to be inflamed and thickened, or even ulcerated ; and there may be thickening and induration of the coats of the intestine, the result of inflammation and suppuration extending from the immediate locality of the stricture.

In addition to these morbid phenomena, which are usual, other serious changes are occasionally seen in connection with stricture of the rectum. Thus the irritation of the disease may produce inflammation and suppuration in the tissues surrounding the bowel ; one or more abscesses may form, and communicate not only with the bowel at separate points, but open upon the surface near the anus, or in the front of the perineum. Sometimes a communication exists between the rectum and the vagina or the urethra, and more rarely an aperture forms above the stricture, between the bowel and the cavity of the peritoneum.

The connection between stricture of the rectum and fistula, as one of its results, is an important one ; the two diseases are by no means unfrequently met with together. It is supposed by some authorities that the fistulous opening in the bowel is generally seated beyond the stricture, and that the morbid change is owing to the obstruction and subsequent mischief produced by the stricture ; whilst others, among whom is Mr. Syme, are of opinion that the fistulous opening is not owing to the resistance which is offered by the stricture. It is a fact, however, that the opening is not unfrequently found behind the stricture, and that sometimes it is situated over down. In a preparation lately inspected by me, where fistulae were associated with a stricture of the rectum, there was an opening into the bowel above the obstruction, and one situated below the stricture. In another specimen, a fistulous sinus runs up along the side of the gut for half an inch above the stricture. In a patient lately seen by me, where the two diseases were associated, I found, on examination, that the fistulous sinus opened into the bowel just above the stricture. In some of these cases there can be little doubt that ulceration of the mucous membrane is the first step in the formation of fistula ; whilst in others suppuration in the surrounding cellular tissue, and subsequent formation of the sinuses, is the correct pathology.

With regard to the seat of stricture of the rectum, it is found that one particular locality is more disposed to the disease than another. Thus in by far the majority of instances, the contraction is met with at the lower part of the rectum, about an inch or an inch and a half from the anus. Observation on the living body proves this ; and the result of my examination of the morbid preparations in the various museums was to show that, in very nearly one-half of all the specimens, the stricture was

found to exist at a point about an inch distant from the orifice. Next in frequency to this part, the disease is met with at a point varying from two to three inches from the anus; it is occasionally met with at four or five inches; and sometimes the contraction involves that part of the gut which marks the junction with the sigmoid flexure of the colon.

The symptoms which are produced by a stricture of the rectum vary according to the extent and peculiarity of the disease. In some rare cases, even when the obstruction has lasted for years, and has materially narrowed the canal, none of the usual symptoms referable to this disease have been experienced until a short period before death, or an examination after death alone has revealed the true nature of the malady. Usually, however, there are well-marked symptoms. In some instances the patient can trace the commencement of his disease to a particular time, when he will inform us he suffered more or less severe and persistent pain in the lower part of the abdomen, which was followed by great irregularity of the bowels, necessitating the use of aperient medicine; diarrhoea has probably supervened, the motions being tinged with blood; and this has been followed by constipation, preventing almost entirely the natural action of the bowels.

As the disease advances, the constipation increases, and there is a sense of obstruction about the rectum, which causes the patient to strain violently whilst at the closet; the faeces are passed in small quantities at a time, and are much diminished in size, as the bowel becomes more contracted; the general health begins to suffer from the retention of fecal matter in the intestines; the abdomen becomes distended, there is marked dyspepsia, with a loaded tongue and general lassitude; and the patient loses his natural appearance of robustness. The local symptoms also become more severe; there is a continual uneasiness about the rectum; considerable pain attending the passage of the faeces, which is effected two or three times in the twenty-four hours, in a liquid form; the bladder becomes irritable; pain is felt in the loins and down the thighs. Occasionally, a large accumulation of fecal matter having taken place above the stricture, there will occur suddenly from time to time a violent attack of diarrhoea, followed by the most obstinate constipation. In advanced cases, one very troublesome symptom consists in the excoriation and ulceration which is produced around the anus by the acrid discharge which takes place from the seat of the stricture. In some cases this discharge is very abundant at the time the patient is at the closet, and is one of the most important diagnostic symptoms.

Although the general health in many cases of stricture of the rectum does not suffer much at first, the disease will, if unchecked, destroy life gradually by the local irritation and suffering, and by the impairment to nutrition almost surely following from constant and long-continued obstruction to the passage of excrementitious matters. In other cases the patient dies suddenly, from symptoms of acute obstruction and inflammation of the bowels, the strictured canal becoming blocked up either by an accumulation of hardened faeces, or by some foreign body. In one remarkably interesting preparation in the Museum of the College of Surgeons, a stricture of the rectum which had existed for years had suddenly become entirely closed, lymph being produced by the irritation of a fishbone which had been swallowed, and which had become arrested at the contracted part.

When the stricture is situated, as it usually is, within two inches of the anus, it is readily felt by the finger, which should be well oiled and carefully passed, because in many cases great pain is experienced by the patient. When the stricture is but slight, involving a small extent or a portion of the circumference of the bowel, the diagnosis will not be so easy as is imagined; when, however, the stricture, as is for the most part found, has encroached on the cavity of the rectum to some extent, the finger readily detects it; for its point becomes entirely arrested by the dense and hard obstruction, or it can only be just insinuated through the diseased part. When withdrawn, the finger is generally covered with a muco-purulent secretion, if the case is at all advanced.

If the symptoms are well marked, and yet the finger cannot reach the obstructed

point, it will be necessary either to make the patient strain violently, or to examine him whilst in the upright posture; in this way a stricture which is situated beyond the reach of the finger in an ordinary examination, may be discovered. Should this fail, a wax or gum-elastic bougie, about as large as the adult forefinger, and well oiled, should be carefully introduced up the rectum. This measure, however, is rarely necessary for the mere purpose of diagnosis, and is open to several sources of fallacy.

In making an examination of the rectum, the surgeon must bear in mind that it may be pressed upon by bodies external to the bowel. An abscess of the prostate gland, especially if of a chronic nature, will so press upon the rectum as to contract its cavity and prevent the passage of the contents of the bowel.

I had a patient at the Westminster General Dispensary, aged 25, who applied with symptoms of obstruction of the bowels; nothing had passed for a week, and he was in continual suffering, and had become very much reduced in health. On examining the rectum with the finger, I found that the cavity of this gut was almost closed by a large elastic tumour situated in front. The patient had not had any gonorrhoea, but about a month since a catheter had been introduced, and had caused severe pain and bleeding. Since then he had complained of pain and weight about the rectum, and the constipated condition of the bowels alluded to had occurred. I suspected that there must be a chronic abscess mechanically preventing the passage of the fæces, and therefore passed a bistoury into the bowel, and made a free incision into the tumour; a large quantity of matter was evacuated, with great relief. The patient was ordered a dose of purgative medicine; this acted freely; and all symptoms of obstruction soon passed away.

The enlarged prostate itself in old people may so press upon the rectum as nearly to obliterate its cavity; the uterus may be retroverted, or a solid tumour growing from that organ may so press on the bowel as to cause the symptoms of stricture. We have seen that the essential pathological feature in stricture of the rectum is a fibrous deposit in or between the tissues of the bowel; and there can be no doubt that the chief instrument in the formation of this product is inflammation of the coats of the intestine of a more or less chronic character. The causes of the inflammation leading to the formation of stricture are various: spontaneous inflammation of the mucous membrane may arise; or the habitual presence of hard fecal matter, exciting frequent attempts to evacuate, will produce it; foreign bodies lodging in a portion of the rectum for a continuous period will bring about the same result. Muscular contraction may cause stricture. I have alluded to one specimen where this, with very good reason, is supposed to have been the cause. Some of the most severe instances of stricture of the lower part of the rectum, or, more properly speaking, of the anus itself, are produced by the cicatrization resulting from wounds made by the scissors in the removal of external piles, especially if the precaution be not taken to excise only the superabundant textures.

Sometimes, in these operations, large portions of skin, as well as circular fringes of mucous membrane, are cut off; the consequence is, the formation of a tight contraction at the anus. I met with an instance of this kind in the person of a lady who had been operated upon for external piles by one who did not understand his business. Such a tight and unyielding contraction occurred as nearly proved fatal; and the only manner in which life could be rendered at all comfortable was by passing a bougie daily, for the patient would not permit me to divide the stricture.

A by no means infrequent cause of stricture of the rectum is ulceration of the mucous membrane of the bowel, terminating in cicatrization and subsequent contraction of the cavity of the intestine. This is occasionally witnessed in those persons who have lived a long time in India, and have suffered from dysentery. Direct injuries to the bowel will produce stricture, such as the operation for fistula, or the infliction of a wound by means of a bougie or an enema-pipe.

There is one cause, however, of stricture of the rectum which is almost entirely overlooked by the majority of writers, in this country at least. I allude to the venereal poison. As a direct consequence of the application of the poison to the part by means of unnatural intercourse, it is doubtless extremely rare in England; but as one of the sequels of syphilis, and as one of the indications of constitutional taint, I believe it is not unfrequently met with. Independent of other instances,

two well-marked cases of stricture of the rectum occurring in respectable married women, who had suffered severely from constitutional syphilis, have lately been under my care. In either case the disease distinctly ensued after the venereal poison had been received into the system. Mr. Henry Lee has informed me that he has lately seen three cases of secondary syphilitic stricture of the rectum. Mr. Partridge assured me that he had a case in King's College Hospital where there could be no doubt that the disease was produced by unnatural intercourse. Bushe, in his valuable work, says: 'Venereal ulceration of the rectum may arise from direct application of the venereal poison; or it may be consecutive to disease in the genital organs, and then co-exists with other secondary symptoms.'

The treatment of stricture of the rectum must be conducted upon the same principles as obtain in the employment of remedial measures for stricture of the urethral canal; and in the first place it must be stated that the surgeon can rarely cure, in the full sense of the word, an organic stricture of the rectum, but he can remedy it in a great measure, prevent its increase, and thus ward off those secondary ills which, almost necessarily, ensue if the original disease be neglected.

The great object the surgeon has in view is to remove the contraction, and to restore the calibre of the gut as nearly as possible to its natural condition. This can in a great measure be effected by the employment of dilatation in the majority of those cases which are situated within the reach of the finger, and where the primary and secondary morbid changes have not proceeded to a serious state. The agent employed is either the bougie, or some other mechanical contrivance for acting on the stricture as a dilator. The bougie which is most generally used is either made of wax, of gum-elastic material, or of metal. As, in the treatment of strictures of the urethra, various surgeons prefer particular kinds of dilators, so it is in dealing with stricture of the rectum, although one form of instrument may be as useful as another. The wax bougie is a most admirable instrument in the slighter forms of stricture of the rectum, where much pressure is not required; it is also a good form to employ in cases where considerable pain is experienced on the introduction of the finger, or where, from the existence of much muco-purulent or sanguineous discharge, ulceration of the mucous membrane is suspected. It is important to be very particular in cleaning bougies after use. The gum-elastic bougie is the one, perhaps, which is most generally useful when well made. It is sufficiently firm to compress the stricture well, and yet elastic enough to yield to any obstruction through which it is not intended to pass. The metallic bougie, which is a short cylinder attached at pleasure to a handle, is especially useful in narrow strictures attended with a large amount of induration and situated close to the anus.

When the stricture is seated beyond the reach of the finger, the use of the bougie is attended with more difficulty, as there is no certain guide to the exact position of the stricture, or to the size of the instrument which it will admit. With very great care, however, the surgeon may dilate a stricture when it is situated several inches beyond the anus with safety: but it must be borne in mind, that the folds of the bowel or the prominence of the sacrum present themselves as obstacles, which may be mistaken for stricture. And the greatest possible care should be taken not to do mischief; it is a well-known fact that in several cases the walls of the gut have been penetrated by the bougie even where there has not been any stricture in existence.

It has been stated that, in certain instances of stricture of the rectum, there has been a venereal origin; and when this can be pretty clearly made out, the local treatment should be assisted by the exhibition of small doses of mercury and iodide of potassium; the general health will be improved, and we may expect a more speedy absorption of the morbid product constituting the stricture. It will be well also, instead of using oil, to smear the bougie with the strong mercurial ointment.

Incision of the strictured portion has been practised by some surgeons; and, as an adjunct to dilatation, it is, in certain instances, a useful means. It is not, however, free from danger. A case came under my observation a short time since, in which death ensued upon the division of a stricture with the knife, and several

similar cases have been recorded. This procedure, therefore, should not be adopted unless there is a necessity for it.

Incision is necessary in those cases of stricture, rarely met with, which are of traumatic origin, and situated at the verge of the anus, or within a very short distance; there is generally a dense cicatrix and much induration around, so that dilatation by the bougie is painful and difficult. It is also advisable, if not actually necessary, in old-standing instances of the disease situated in the usual locality and arising from the usual causes, but where, from neglect and continual irritation, the induration around has become excessive, and the stricture most unyielding to the bougie. In either case the operation is best done by introducing the left forefinger into the rectum, and guiding upon that a straight, blunt-pointed, narrow bistoury, with which the stricture is to be divided. Deep incisions must not be made, but the stricture should be simply notched at several points of its circumference. A bougie should be introduced immediately for a minute or two; a suppository of opium is then to be passed into the rectum; the patient must keep quiet for two or three days, when the bougie is to be employed, and continued at regular intervals. In this manner a stricture which previously had defied all attempts to dilate it, will be so far reduced that the patient may obtain great comfort.

A stricture of the rectum when once fully formed, is seldom or never thoroughly cured, even under the most assiduous care. There is the same tendency to re-contraction here as in instances of stricture of the urethra; therefore, when the disease has been brought under subjection, it will be absolutely necessary to keep up periodical dilatation; this may, however, be easily effected in the majority of cases by the patient himself. In some cases once a week will suffice; where, however, the disease has been traumatic, it will be needful to pass a bougie every day, or every other day, to prevent re-contraction.

When sudden obstruction of the bowels takes place in an instance of stricture of the rectum situated high up beyond the reach of the finger, the patient is placed in the most formidable danger, for it is impossible to ascertain the nature of the obstruction. I have referred to one preparation in the Museum of the College of Surgeons, showing a stricture of the rectum situated near the colon, which had become suddenly closed by an effusion of lymph, the result of a fish-bone sticking in the stricture.

In such cases the long tube must be carefully passed, and the obstruction may be overcome; a large quantity of warm water should then be thrown up. If, however, it is found that the tube cannot be passed, and the use of powerful purgatives is of no avail, death will be imminent; and the only chance of obviating it will consist in making an opening into the colon, either by the method adopted by Littre in the groin, or that suggested by Amussat. The latter operation is that which is usually selected; there are a few cases on record where life has been preserved, and there are instances in which the surgeon is undoubtedly justified in resorting to this expedient.

CANCER OF THE RECTUM.

In considering the subject of stricture of the rectum, that form of the disease only has been alluded to which is the result of simple inflammatory thickening: there is, however, another condition, where more or less obstruction to the calibre of the bowel is produced by growths which are essentially of a malignant character, whereby the constitution is contaminated, and which render the local disease much more formidable than the simple stricture. The features of distinction between these two particular kinds of the affection are generally pretty broadly marked, and, indeed, cannot well be confounded, when the one we are considering has become fully developed.

Cancer may attack any part of the rectum, but it is perhaps most generally met with in the lower portion; so that in a large number of cases the disease is within the reach of the surgeon's finger, and its character may be readily appreciated. In the very early stage of the disease it appears to commence as a hard deposit between the

coats of the intestine; the deposit in some instances consisting of distinct nodules scattered here and there over the bowel; in other cases there will be a complete circle formed by the disease. The actual seat of the deposit is in most cases the areolar tissue, between the mucous and muscular coat. As the disease advances, this is more distinctly ascertained by the circumstance that the mucous membrane, in a more or less healthy condition, is raised up by the deposit underneath it; in course of time, however, this membrane becomes ulcerated, generally in the centre of the deposit.

In more rare instances the malignant deposit is situated between the muscular and serous coat of the bowel, and the morbid growths penetrate into and between the fibres of the muscular tissue. A general thickening and induration of the whole structure of the bowel takes place, so that when a section is made it is impossible to distinguish one texture from another. By this means the cavity of the bowel becomes encroached upon, much in the same way as when the simple fibrous thickening takes place.

As time advances and the cancerous growth increases, the cavity of the intestine becomes encroached upon to a greater extent by the formation of one or more tumours, or nodules, which project into the bowel; by-and-by ulceration of their surface takes place, and in some instances there will be found blended together a large hard nodule of cancer, and a distinct fungous growth with a bleeding ulcerated surface. The morbid growths increase upwards and downwards, and involve the rectum to the extent of four or six inches, and spread towards the orifice of the bowel, and appear there as warty growths or masses of fungoid disease. It not unfrequently happens, however, that there is a small portion of the bowel perfectly healthy between the anus and the deposit.

All the different varieties of cancer are seen to involve the rectum; of these, however, the true hard scirrhus is that most frequently met with. Encephaloid and epithelioma are not unfrequent, and colloid cancer is occasionally seen.

The symptoms which attend upon malignant disease of the rectum vary much, both according to the stage of the malady and the particular effect the deposit has upon the cavity of the bowel. At the outset the patient complains of an uneasiness about the lower part of the bowel, and an interruption to its proper functions; the fæces passing with more difficulty than heretofore; diarrhoea occasionally intervening, accompanied with bloody mucus, and this latter symptom becomes more and more prominent. Thus at first the symptoms are those which depend upon ordinary stricture of the rectum, and the more especially as in some instances there is very little disturbance of the general health. As the disease advances, however, there comes on a greater difficulty in voiding the fæces, the act is accompanied with considerable pain, and at each time the bowels are moved there is a discharge of blood. As in ordinary stricture, there is great distension felt, which is now and then relieved by a profuse diarrhoea.

The general health at first is but slightly affected; but as the disease advances, its effects on the constitution become marked; the patient complains of indigestion and flatulence, and of an indescribable depression. His face becomes anxious—presents the peculiar dull aspect of one suffering from malignant disease; and emaciation takes place. The patient is deprived of rest; and indeed there can be few more pitiable objects than some of those who are suffering under cancerous disease of the rectum.

In course of time, the gut becoming more narrowed, and the surface of the diseased textures getting into an ulcerated state, there ensues of necessity a greater hindrance to the passage of the fæces; painful attempts are constantly made to pass them, and these efforts are accompanied with an acrid sanious discharge, mixed with feculent and muco-purulent fluids. And frequently this action comes on without the patient having the least control over himself. As the disease involves the surrounding tissues, abscess forms by the side of the bowel, and degenerates into fistula. And when the deposit encroaches upon the bladder, there is either great irritability of that organ, or daily retention of urine; this latter symptom may

be produced by the impaction of fecal matter in the urethra. I have lately seen a preparation where a fatal retention of urine proceeded from this cause.

Death generally follows this disease within three or four years after its symptoms are marked. And it is produced either by a gradual sinking of the powers of life, or by the sudden coming on of an attack of obstruction of the bowels.

FIG. 175. Cancerous Growth, protruding at the Anus, surrounded by external Piles.

When the disease has existed for some time, and is not situated high up in the bowel, the surgeon can have little difficulty in forming a correct diagnosis; and in many cases there is more or less scirrhus induration at the orifice of the anus, or the disease protrudes externally in the shape of a fungoid mass. In the early stages, however, it is not easy to recognise the true nature of the malady. If the growth be within the reach of the finger, it will be felt as an indurated ring, encircling, or partially encircling, the bowel, as when a simple stricture exists; but in the scirrhus disease the hardness is much more decided and more extensive, the discharge also of a more offensive and sanious character than it is in the earlier stages of the simple stricture. It may, however, be difficult notwithstanding to ascertain the true nature of the malady at its outset; therefore a cautious opinion must be given.

I saw a patient, about 40 years old, who was operated upon twice for fistula, neither operations succeeding. On going to see her after the last had failed, I made a careful examination, and discovered a stricture at the lower part of the rectum. I am not aware that there had been any suspicion of malignant disease, and the only reason which made me suspect its existence was the circumstance of the induration being very decided and extensive. I gave a cautious opinion, inclining rather to the view that the disease was malignant. This patient has lately died with cancer of the rectum. I may mention that the surgeon who operated upon the fistula was a man of large experience and great skill.

The *treatment* to be adopted for malignant disease of the rectum can offer no other service, unfortunately, than that of palliating the disease, assuaging pain, and prolonging the duration of life. We have seen that, in instances of simple stricture of the rectum, the affection may be cured, or at all events kept under control, by the careful employment of proper surgical means and appliances; because the deposit forming the contraction is merely the result of inflammation, and thus may be absorbed or much diminished by the use of pressure; and moreover, the general constitutional health is not affected as when the disease is of a cancerous nature. Relief, however, can be given to those unfortunate persons who labour under the latter complaint; and it is important to inquire what are the measures best calculated to produce that relief.

There is a difference of opinion amongst surgeons as to whether the employment of dilatation is proper. As a rule, it may be stated that bougies should not be used in malignant stricture of the rectum; but it is unwise to discard them entirely. When the disease is met with in its early stage, has not ulcerated, is within reach of the finger, and is producing much contraction of the calibre of the bowel, a wax bougie well oiled may be passed gently through the contracted part; and its use may be repeated once or twice in the week, if pain be not produced. In a case of extensive cancer of the rectum which had not ulcerated, I employed the bougie in this manner for a long period with the effect of giving relief. It is not to be expected that any absorption of the diseased tissue should take place beyond that which is deposited in connection with cancerous stricture as the mere result of inflammatory

action. When, however, the disease has advanced to the ulcerative stage, it would be highly imprudent to use bougies.

The main object in the treatment is the alleviation of pain; and this is best effected by the use of anodynes exhibited in the shape of suppositories made of pil. saponis comp. or of morphia mixed with extract of hyoscyamus, in the proportion of half a grain of the salt to ten grains of the extract. This should be introduced each night into the rectum, and in the course of time the strength of the anodynes must be increased. I have seen very great relief given to the patient for many weeks by the use of this suppository. As the disease extends, and involves other parts, the suffering is much more severe, and it will be found necessary to give opium by the mouth as well as by the rectum, in order to produce a mitigation of pain.

The bowels are to be unloaded by the occasional use of aperients, and, when there is not much irritation caused, by the exhibition of enemata of warm water. In order to soothe the ulcerated and painful parts, injections of tepid oil or of decoction of poppies must be used from time to time: the surgeon must not forget to take great care in the introduction of the enema-tube, as serious mischief may soon be effected.

During the time the malady is running its course, the strength of the patient, which will gradually decline from day to day, must be supported by those articles of diet which contain the most nutriment in the smallest bulk, and which leave but little feculent matter in the intestines; and it will be needful to avoid as much as possible vegetables and bread. The profuse sanious and foul discharge which sometimes accompanies this disease may be checked by an injection composed of sulphate of copper and opium, or a very diluted lotion of solution of chloride of zinc may be employed with benefit.

If sudden and complete obstruction of the bowels should occur during the course of this disease, it will be a question as to how far the surgeon is justified in making an artificial anus. If this accident happens in the last stage of the disease, when the patient is much exhausted by previous suffering, I do not think that the operation should be performed; but if the obstruction, which must be fatal, should occur during the earlier course of the affection, and before the constitution of the patient has been much impaired, the surgeon is only doing his duty if he recommends a proceeding which, although in itself surrounded with difficulty and danger, may yet prolong life for several months at least, and allow the patient to die at last in comparative ease. Some surgeons were, a few years since, in the habit of performing excision of the lower part of the rectum when affected with cancer. Mr. Harrison Cripps has paid great attention to this subject, and is an advocate of the operation, and, in his work recently published, has shown that in certain cases great benefit may be accomplished by the operation. It is, however, one surrounded with so much danger and difficulty that it is only, I think, in rare instances, where the disease is limited to the lower two inches of the bowel, and where the finger can be got well behind the diseased part, that the surgeon is justified in performing it. The operation may be effected by the knife alone, which is the most speedy and perhaps the best method, or, after the incisions have been made, the *écraseur* may be used to separate the growth, or the thermo-cautery: by this means loss of blood may be prevented.

In one case I removed the lower two inches of the rectum for a scirrhus tumour; it was in the person of a woman aged 60, otherwise in good health. The growth was well defined, and could readily be commanded by the finger introduced into the vagina. The mucous membrane of the vagina could be freely moved over the growth; and, although it extended into the ischio-rectal fossa considerably beyond the anus, implicating the skin and anal orifice to such an extent as almost to close it, still it was quite circumscribed; and under these circumstances I did not hesitate to remove it in the following manner. I introduced the finger into the rectum, carrying its point to the top of the coccyx. I then introduced a sharp-pointed curved bistoury along the finger to the median line posteriorly, and cut outwards. I then made an incision through the skin about an inch from and on each side of the anus, carrying them forward until they met at the posterior part of the vagina. The bowel was carefully dissected away from the vagina, and isolated with the knife; the finger during this dissection being kept in the bowel, upon which traction was made. Very free hæmorrhage took place during this part of the proceeding. In order to check this, and at the same time

complete the severance of the bowel, I used both the cutting and serrated cautery employed by me in removing hæmorrhoids. The vessels which bled were thus secured, and the edges of the severed bowel were stretched to the integument on either side and behind, and a drainage-tube left in.

The patient lost a very large quantity of blood, and remained for some time in a state of collapse, but she soon rallied, and received great comfort from the operation.

POLYPUS OF THE RECTUM.

Polypus of the rectum is not unfrequently seen by those who have large opportunities of studying the affections of this portion of the intestinal canal. It is met with in various forms, and it is important to be acquainted with the disease, inasmuch as it often produces most severe symptoms, and at the same time is easily remedied.

The most simple form in which a polypus is seen is where there are one or more short processes, as it were, of the mucous membrane standing out prominent in the cavity of the rectum. These bodies, if they may be so termed, produce little uneasiness, and are generally only accidentally discovered when the surgeon is, making an examination of the bowel with the speculum for some other disease. They are usually situated above the sphincter, cause very little inconvenience, and therefore do not demand the attention of the surgeon.

The soft gelatinous polypus, like that growing from the mucous membrane of the nostril, is very rarely indeed met with: but it is not an unfrequent occurrence to observe a polypus which grows from the mucous membrane of the rectum about an inch from the orifice. It varies in length and thickness, being from half an inch to two inches in length, and as thick as a crow-quill or as the little finger. This form of tumour is of a reddish-white colour, firm in texture, and attached to the mucous membrane sometimes by two distinct stalks; or it may have only one attachment and a bifurcated extremity. On examination this form of polypus is found to be fibro-cellular in structure, and very slightly vascular. In one specimen of this fibrous polypus, which I lately removed from the mucous membrane of the gut just within the verge of the anus, some curious microscopical appearances were observed. The structure was principally fibrous, but the mucous covering was arranged so as to form a number of very distinct villous processes. It looked like a piece of small intestine; lacteals could be seen in the villous processes, and their trunks could be followed for some distance into the tissue of which the tumour was composed.

When seated high up, this polypus does not produce much uneasiness; but most generally it is attached to the bowel so near to the anus, that when the patient is at the closet the extremity of the tumour protrudes, and perhaps becomes gripped by the sphincter, and in this manner very annoying and painful symptoms are produced. Sometimes even the polypus protrudes when the patient walks about; great irritation exists; there is a discharge of mucus, sometimes of a little blood; and the patient is obliged to wear a support, which gives ease. He is conscious of some foreign body at the anus, but the symptoms are usually attributed to piles.

The only efficient treatment for this kind of polypus is to remove it; and as there is so little vascularity, it may safely be taken away by the scissors, especially when the tumour is very near to the anus; for if there be any hæmorrhage, it is easy to stop it. When the polypus is situated an inch or more above the anus, and the base is at all broad, the tumour should be well brought down by an injection previously given, and a thread can be tied tightly around the base before the growth is snipped away. In several cases, however, where I have cut these fibrous polypi away without first tying them, there has only been a very slight amount of bleeding subsequently.

A form of polypus very rarely met with is where the growth is warty.

I lately saw a gentleman of middle age, who consulted me for prolapsus; and on coming to examine him, after making him protrude the parts well, I found attached to the base of the prolapsed portion, about an inch from the verge of the anus, a curious-looking mass, composed of an aggregation of small lobes arranged upon a peduncle, just like a bunch of

grapes. This polypus, if it may be so termed, was an inch in length, of a reddish-white colour, and it protruded at the centre of the anus. I removed this growth; and on microscopical examination its texture was chiefly or entirely epithelial, in fact it might be considered as a warty growth.

The *vascular* polypus is, perhaps, of most frequent occurrence; it is chiefly met with in young children. The tumour varies in size from a cherry to a pea; is of a bright red colour; its structure is fibro-cellular, and eminently vascular. It is either situated within a short distance of the anus, or it may have its attachment one or two inches up the gut, by means of a long narrow stalk. The symptoms which this form of the disease produces is the prolapse of the tumour on the child evacuating the bowels, and hæmorrhage of a more or less profuse character. This bleeding not only takes place when the child is at the closet, but it will persist afterwards, when he is running about. The occurrence of this loss of blood in a child should lead to a close examination of the rectum for polypus; for if the tumour be attached high up, it will recede immediately after the action of the bowels, and escape observation. It is necessary, therefore to make the inspection immediately after the evacuation of the contents of the rectum either by medicine or an enema.¹

The treatment which should be adopted is simple, and merely consists in the removal of the polypus, either by twisting it off with a pair of forceps, or placing a ligature around the pedicle, and returning the tumour within the bowel and allowing it to slough off. Excision should not be resorted to in these cases, as there might be a considerable amount of bleeding, which would be especially prejudicial in a young child.

A rare form of polypus of the rectum is occasionally met with in adults, when the tumour reaches a size as large as an egg; it has been not inaptly termed the *villous* tumour, inasmuch as it mainly consists of elongated processes or villi, extremely vascular. This form of tumour produces most severe symptoms of a foreign body in the bowel, and is the cause of periodical hæmorrhage to a large extent, by which the health becomes very much broken down. It is a question with some as to whether this form of polypus is malignant or not.

Mr. Quain has made some investigations into the structure of this tumour, and he has found that it was composed of long processes slightly held together, each process strictly resembling villi. And as the mass is very vascular, he has concluded that the disease is not of a malignant nature, as stated by Rokitsansky.

¹ It is very important to make a thorough examination of the rectum immediately after the bowels have been acted upon, when there is a suspicion of a polypus, otherwise the disease may escape notice. A remarkable illustration of this occurred in a lady to whom I was called by a medical practitioner, who had been in constant attendance upon the patient, whose symptoms were referred to some external piles. These were removed, but with scarcely any relief to the severe pain experienced after the action of the bowels, and to the sense of protrusion. I made a careful examination, after the bowels had been well cleared with an enema; but nothing was observable beyond a slight crack at the posterior part of the anus. It was thought right to divide this, in the hope that the severe pain would be removed by the operation, but this failed in its object; and we were vainly endeavouring to ascertain the cause of her suffering, until on one occasion we found the patient had just got into bed after having had the bowels freely acted upon. I took the opportunity of examining her immediately, and to my great surprise found a large fleshy polypus attached high up to the posterior wall of the gut by a narrow peduncle. Without further delay, I, with some difficulty, placed a double ligature around this tumour, and thus fortunately removed a disease which, from being long undetected, had caused great suffering. It was strange that this polypus had not shown itself when I examined her on a previous occasion after the action of the enema.

FIG. 176.—Warty Polypi at the Anus.

A very interesting specimen of this rare form of tumour of the rectum is preserved in the Museum of St. George's Hospital, and on examination it presents exactly the features

FIG. 177.—Villous Tumour of the Rectum.
(From a preparation in the Museum of St. George's Hospital.)

described by Mr. Quain. It was situated about three inches from the verge of the anus, in the anterior wall of the rectum, evidently springing from the submucous cellular tissue. It is round in form, circumscribed and prominent, and about the size of an orange. The tufts or processes are remarkably well developed. The tumour so obstructed the cavity of the bowel, that almost complete retention of the fæces resulted, and the gut above was very much distended. The bladder was much pressed upon by the diseased mass. It was impossible to say how long the disease had been growing, but it was not detected until about five years before death, when the occurrence of hæmorrhage and of the symptoms before spoken of led to its discovery. Several attempts were made to destroy the mass by ligature and other means, but it was not possible to effect more than a partial removal of the more prominent portions—an operation which was performed no less than thirty-three times before his death, and on each occasion with temporary benefit. The patient was 70 when he died, and no other disease was found on a careful examination of the body.¹

I have only once met with an instance of a growth of this nature, but it was of a very interesting character, inasmuch as it had resisted treatment and had reduced the patient to a very low state. It was that of a married lady, sent to me by Dr. Rooke of Cheltenham. She had suffered much from profuse hæmorrhage from the bowel without any protrusion whatever, and when I first saw her it was extremely difficult to ascertain where the bleeding came from, but after a very careful examination with the speculum, I found a well-defined vascular growth, about the size of a crown-piece, two inches from the anus. From the condition of the patient, and the appearance of the diseased parts, I was afraid that it might be of a malignant character, and this idea was somewhat confirmed by the continuance of the bleeding, notwithstanding very careful local and general treatment. However, finding milder measures fail, I determined to apply with vigour strong nitric acid to the part. This I did on several occasions, and was much pleased to find that the bleeding became checked, and after about half-a-dozen applications the hæmorrhage ceased, and the patient's health was rapidly restored. I saw this lady lately, some three years after the treatment, and she was in remarkably good health.

PRURITUS ANI.

This affection is very common, and very productive of suffering; and, although, certain pathological changes occur at the margin of the anus in connection with it, itching and irritation of this part must be regarded rather as a symptom than as a special disorder. Thus it is frequently associated with an unhealthy state of the secretions of the intestinal canal, or with simple constipation—a fact which is not uncommonly overlooked in the treatment of those who suffer; it is also attendant upon a congested state of the vessels of the rectum, which can hardly be considered hæmorrhoidal, inasmuch as on examination there will be found neither hæmorrhoidal tumours nor prolapsus, but a considerable amount of congestion of the mucous membrane. This form of the complaint is peculiarly prone to occur in those who sit for a long time together at the desk. Pruritus is familiar to us as a symptom of ascarides in the rectum; it is also found in a very distressing degree in connection with disordered condition of the womb. I have recently seen a case of ulcer of the rectum, where the only well-marked symptom attending upon this usually painful morbid condition was a constant and troublesome itching.

Certain morbid changes occur around the margin of the anus in advanced cases of this disorder, in consequence of the attempts of the patients to relieve themselves

¹ *Phil. Soc. Trans.* xii. 120.

by scratching and irritating the parts; the naturally thin skin becomes excoriated; the secretions of the part are exaggerated; and if the irritation is continued, fissures, and even ulcerations, are formed; and in course of time the integument becomes thickened and indurated, and gets almost into a condylomatous state; and a painful and distressing itching is produced—especially when the patient lies down in bed—which is most troublesome to remove.

In these cases there will be generally found some morbid alteration, in the form of slight ulcerations or fissures of the skin, and the first object is to heal these; and it may be effected by the very careful application of a solution of nitrate of silver—of a strength varying from ten to twenty grains of the salt to an ounce of water—by means of a camel's-hair brush. The application should be repeated so long as the cracks or ulcerations exist. Not unfrequently the itching and irritation will disappear as soon as these heal and the skin becomes healthy; but there is a tendency for the excoriations to reappear; and to prevent this, the patient should be advised to bathe the parts well morning and night with a strong solution of alum. If the solution of nitrate of silver fails either to heal the fissures or to give relief to the itching when they are healed, an ointment composed of one drachm of glycerine to an ounce of lard may be used with good effect; and should there exist a thickened or condylomatous condition of the integument, I know of nothing more useful than the application of an ointment composed of one drachm of calomel and one ounce of lard. If an ulcer—as in the case mentioned before by me—should be found to exist within or upon the sphincter, the ordinary operation for that malady must be put in force.

In some obstinate cases, it will be found that the use of all the usual measures, general and local, will be unattended with relief. If it has not already been tried, I am in the habit of recommending the daily introduction of a well-oiled bougie made of black wax.

NEURALGIA OF THE RECTUM.

It is perhaps impossible to affirm with truth that neuralgia, as it attacks other parts of the body, is ever situated in the rectum; but every now and then cases are met with where extreme suffering of a distinctly neuralgic character is experienced for a long period, and where, on the most careful examination of the parts, both external and internal, no appreciable lesion can be found; and we therefore do not hesitate to apply the term neuralgia to this condition of things. The cases are more frequently met with in the persons of females who have been lowered by some depressing causes; the pain is described as being very severe and continuous, and not particularly aggravated by the action of the bowels, as is the case when the suffering is produced by a painful ulcer of the rectum. It may be of a marked periodical character, and be the result of direct exposure to cold.

The cure of this affection is extremely difficult, and indeed sometimes only a temporary relief can be given. Of course, when a patient applies with the symptoms of neuralgia, the most careful examination of the parts should be instituted, and repeated from time to time; for doubtless in some of those cases which have been supposed to be neuralgia, there has been some lesion which has been overlooked. If, however, nothing of the kind can be met with, a similar treatment to that which is put in force for neuralgia in other parts should be adopted, due regard of course being had to the removal of any local irritant from the bowels in the shape of hardened feces; iron and quinine in large doses should be exhibited, especially in those cases where there has been any lowering of the system; should there be any tendency to gout—a point not to be overlooked in our inquiries—colchicum should be prescribed. The local remedies best suited for this complaint are, the employment of the cold douche to the anus, and the use of belladonna ointment, in the proportions of one drachm of the extract to one ounce of lard, either smeared around the anus, or introduced up the rectum by means of a large wax bougie. Should the latter measure be adopted, care should be taken to watch the effects of the belladonna on the system.

HENRY SMITH.

GENERAL DISEASES OF THE SKIN.

THE classification of skin diseases which I shall adopt in this article is substantially that originally proposed by Plenck of Baden, and adopted with some modification by Willan, and subsequently employed by a large number of writers on the subject. At the same time I shall deviate from Willan's arrangement widely in one or two important particulars. The microscope, by revealing the presence of parasitic plants in certain of the diseases of the skin, and the close study of these same diseases, by which the relation between the plant and the disease has been ascertained, enable us to found a new order, and so, by abstracting certain diseases from some of the orders of Willan, to render those orders infinitely more natural.

The faults in principle of Willan's arrangement are many and obvious; but it is eminently practical. The diseases grouped together in his arrangement by no means agree pathologically; but his divisions greatly facilitate diagnosis; they enable the name of a particular case of disease to be learned, and this being learned, its pathological and anatomical position may subsequently be determined.

Order 1. *Exanthemata*.—The diseases of this group have, as their great characteristic, redness, disappearing or diminishing transiently on pressure. The cutaneous affection is essentially nothing more than an increased quantity of blood in the vessels of a portion of the skin. Now and then, however, the blood accumulates in such quantity at particular points as to cause a little elevation of the cutis; and if these points are small and circular, we have an appearance of papulæ; but the elevation, like the redness, disappears on pressure; to return, however, when the pressure is removed.

The connection between the hyperæmic cutis and the cuticle covering it is usually diminished either before or during the stage of resolution; and the consequence is, that there is generally a little desquamation of the cuticle while the rash is fading, or after the redness has disappeared. It is probable that the loosening of the cuticle is due to the effusion of a small quantity of serosity from the engorged vessels of the surface of the cutis. Now and then, indeed, fluid is effused in sufficient quantity to raise the cuticle from the cutis; thus in the eruption of scarlet-fever it is common to find innumerable vesicles stud the red surface; and in erysipelas the cuticle is occasionally elevated into bullæ. Besides certain eruptive fevers and erysipelas, the exanthemata include erythema, roseola, and urticaria.

Order 2. *Hæmorrhagia*.—In the exanthemata the blood is within the vessels of the red part; in the order hæmorrhagia the blood escapes from its vessels into the substance of the cutis, and so crimson spots unaffected by pressure are formed. There are only two diseases thus distinguished, viz purpura and scurvy. But hæmorrhage into the substance of the cutis occurs not unfrequently in the course of all diseases of low type. If the hæmorrhagic spots be small, they are termed petechiæ; if large, vibices or ecchymoses. When small, the spots formed by cuticular hæmorrhage are usually circular; at the bend of the elbow, however, they are oval. When large, they are often very irregular in form.

Order 3. *Vesiculæ*.—These diseases are characterized by the development of vesicles, i.e. of minute collections of serous fluid seated immediately under the cuticle. Although at first transparent, this fluid ordinarily becomes in a short time opalescent, milky, or even puriform. The cuticle covering it is also at first quite transparent; after a while, however, it, like the fluid beneath, grows white and opaque. This

change in the cuticle may precede that in the contents of the vesicle. The fluid of a vesicle is formed on the surface of the cutis, directly beneath the cuticle. The fluid from a vesicle may be absorbed, or it may dry up and form with the cuticle over it a thin scale; this scale may be detached, or it may remain attached and be thickened by fresh secretion beneath it.

If the vesicles are very small and numerous, and the fluid in them contains but little solid matter, then a mere furfuraceous desquamation follows their bursting, or their desiccation; under these circumstances the vesicular nature of the disease may be overlooked, and the desquamation of the cuticle only noticed.

If the fluid contains a large amount of solid matters, or if the scales first formed be thickened by the drying on them of fresh secretion, then flat scabs of a yellowish-brown colour are formed. These scabs are often raised at the circumference. Dry or moist honey-like scabs are never formed by the drying-up of vesicles.

It has been said that vesicles are formed at the orifices of sudoriferous ducts; but, although this may be true in some cases, all vesicles are not so constituted. The vesicular diseases are: sudamina, miliaria, eczema, and herpes.

Order 4. *Bullæ*.—The diseases belonging to this order of skin diseases are distinguished by the eruption of blebs or bullæ; that is to say, collections of serosity of considerable size, situated directly beneath the cuticle, and raising the cuticle from the cutis. Bullæ differ from vesicles only in size. They vary in diameter for the most part from a quarter of an inch to two inches, but now and then attain the dimensions of half a hen's egg. The fluid of bullæ, like that of vesicles, as well as the cuticle over them, may be transparent or opalescent. Bullæ may be followed by crusts or by ulcers. Pemphigus and rupia are the only two diseases belonging to this order.

Order 5. *Pustulæ*.—The presence of pustules marks this order. Pustules contain pus from the moment of their formation. The inflammation, on which the formation of pus depends, extends some depth into the cutis; so that the collection of pus which constitutes the pustule is situated in the cutis and not merely on it immediately beneath the cuticle.

When vesicles become opalescent, their opalescence depends on the presence of pus-corpuscles and molecular matter; but true vesicles, whether their contents be transparent or milky, are never sunk into the cutis, and the pus-corpuscles when present constitute a very small proportion of their contents.

Pustules are followed by thick and dry or by honey-like crusts.

There are three forms of pustules—viz. *psudracia*, *phlyzacia*, and *achores*.

Psudracia are very little raised above the level of the cutis. They are seated in the hair-follicles—a hair passing through the centre of each pustule. The redness around this variety of pustule is frequently very trifling, especially when the pustules are placed at some distance from each other; when near together, however, the skin between may be red, hot, and swollen.

Phlyzacia are distinct pustules of some size, seated on elevated, inflamed bases. They are found especially on the trunk and extremities, and they terminate in small brown scabs.

Achores are very small pustules on comparatively large inflamed bases; base and collection of pus, however, form together only a small pustule. *Achores* are formed in considerable numbers in the vicinity of each other, the cutis between being red, hot, and swollen. They are more common on the face in children than elsewhere. The secretion from them forms those very large, thick, irregular-shaped scabs, resembling dried honey in consistence, so common on the chins of children. *Achores* are inflamed hair and sebaceous follicles.

Impetigo and *ecthyma* are comprised in the order pustulæ.

Order 6. *Papulæ*.—Papulæ are solid elevations of the cutis of small size, papilliform; their colour varies from dull white to bright red. When red, the colour may be removed for an instant by pressure, but the elevation remains. Papulæ are supposed by some to be enlarged papillæ; but the researches of Gustav Simon prove that papulæ may be formed at any point of the cutis by infiltration of the cutis at that point with serosity.

Three affections belong to the order papulæ, viz. strophulus, lichen and prurigo.

Order 7. *Squamæ*.—The order squamæ is characterised by the formation of an excessive quantity of epithelium-scales loosely attached to each other and to the cutis. By the slightest friction dry opaque white scales are detached from the diseased surface.

Psoriasis and pityriasis are the only affections which strictly belong to the order squamæ. Ichthyosis and xeroderma, however, may be conveniently retained, as Willan placed them, among squamous diseases.

Order 8. *Tubercula*.—Solid hard elevations of the cutis, much larger than papulæ, are called tubercula. In this order are included several diseases anatomically and pathologically very different from each other. The order tubercula includes molluscum, acne, lupus, leprosy, elephantiasis, frambœsia, and keloid.

Order 9. *Maculæ*.—The diseases of the order maculæ are characterised by the presence of too much or too little pigment in the parts of the skin affected, and therefore by white or dark-coloured spots. They are lentigo, ephelis, vitiligo, and nigrities.

Order 10. *Parasitæ*.—The diseases of the skin in which a vegetable parasite is invariably present are tinea tonsurans, tinea favosa, tinea sycosis, and chloasma. Tinea decalvans is also placed in this group.

There is only one disease characterised by the presence of an animal parasite, viz. scabies.

Order 1.—EXANTHEMATA.

Roseola is an acute disease, of trifling importance so far as concerns the safety or the suffering of the patient.

Roseola is so named from its colour. It is characterised by small rose-coloured spots, or by a roseate mottling of the skin. The spots are slightly raised.

All varieties of roseola have a constitutional origin. There is one variety very common in children and young persons of both sexes (hence called by some *r. infantilis*), and especially prevalent in hot weather (and therefore named *r. æstiva*), in which rose-coloured spots and mottling give to the skin an appearance very closely resembling that of measles. From the rash of measles that of roseola *æstiva* differs in the absence of a crescentic form or arrangement of the spots—a character rarely wanting in measles; in the very irregular shape of the patches, and in their more rosy and generally paler hue; in commencing on the most prominent parts of the face and extremities, instead of, as in measles, about the edge of the hairy scalp; in its limitation not uncommonly to a small part of the trunk, or to a single limb; and in its irregular course.

Trifling febrile disturbance usually precedes the rash for a few hours, or it may be a day or two, and dryness and redness of the fauces are common. The coryza, so distinctive of measles, is never observed in roseola *æstiva*. A measles like rash, accompanied by sore-throat, and without coryza, should suggest the possibility of the case being roseola *æstiva*. If more than one child in the same family is affected, the probability is in favour of the disease being measles; but the writer has seen two sisters, after an error in diet, affected at the same time with well-marked roseola *æstiva*. Sometimes those of the greatest experience will be in doubt whether the case be one of roseola *æstiva* or of measles.

The duration of roseola *æstiva* is by no means constant. The rash may disappear in twenty-four hours, or it may remain out for four or five days. Occasionally it appears again after having once vanished.

A roseolous rash resembling this occasionally occurs as an epidemic. It is the disease to which the name bastard measles, German measles, or röttheln, has of late years been applied.

A rose-coloured rash, very similar to that of roseola *æstiva*, sometimes precedes the eruption of small-pox. It occurs especially at the flexures of the joints. The pain in the head and back, and the vomiting, which precede the eruption, indicate the nature of the case, as no such symptoms precede the rash in any other form of

roseola. Sometimes, this variety of roseola bears a close resemblance to the rash of scarlet-fever.

A similar rash may accompany vaccinia, gout, and rheumatism; it may, under these circumstances cover more or less of the trunk and extremities, or it may occur in patches. The specific name is derived from the constitutional disease to which the roseola is secondary, e.g. roseola variolosa, roseola vaccina, roseola rheumatica.

The remaining two varieties of roseola differ altogether in appearance from roseola festiva. Now and then in adults, as well as children, and more commonly on the arms than elsewhere, a few rose-coloured circular spots are seen, varying in size from a threepenny-piece to a shilling. These spots are not elevated, or only very slightly so, and their colour disappears on pressure. As this affection has been thought to be more common in the autumn than at any other period of the year—though its especial prevalence at that time of year is doubtful—it has been called roseola autumnalis. It is a disease of no importance, and may not be accompanied by any general or internal local derangement, though occasionally there is a little febrile disturbance, or some dyspepsia. It rarely lasts more than a week or ten days. On the lower extremities, and sometimes on other parts, we observe several rose-coloured rings, varying in diameter from a quarter of an inch to an inch. The colour of the skin within the rings is quite natural. The rose-red colour is the only deviation of the skin from its healthy state. This form of roseola is named roseola annulata. Like roseola autumnalis, it is usually accompanied by a little febrile disturbance, and runs its course in a few days. Now and then, however, it is a chronic disease, lasting for many weeks.

Treatment.—A warm bath or two, rest, simple diet, and a single dose of mercurial at bedtime, followed by a mild saline aperient the following morning, are usually all that is required in the treatment of a case of roseola. Roseola infantilis is sometimes the consequence of painful dentition; should the gums be hot and swollen, they ought to be scarified. In the chronic form of roseola annulata, the digestive organs are commonly much deranged, and the patient more or less generally out of health. Change of air, mild tonics, such as the mineral acids, and sea-bathing, are the best remedies. At the same time care must be taken to regulate the patient's diet. As the dyspepsia is of the atonic form, a glass or two of wine daily is usually of advantage. As this disease is sometimes dependent on uterine disturbance, the condition of the uterine and vaginal discharges should be ascertained.

The eruptions proper to typhus fever, measles, German measles, typhoid fever, scarlet fever, and cholera are in reality roseola, but differ in important particulars from the varieties just described. The rash of typhus and of measles as much merits the name of roseola as does that which precedes the eruption of small-pox. The mulberry rash of typhus fever differs from the other varieties of roseola by its dusky colour and the petechial character assumed by the separate spots as the disease progresses; the exanthem of typhoid fever by the wide separation of its constituent spots from each other, and their papular form; that of measles by the crescentic arrangement of its spots; the rash of scarlet-fever by its punctiform character, its colour, and the extent of surface covered; that of cholera by the size and irregular form of its spots and their tint. All are distinguished by their course, and by the constitutional disturbance which precedes and accompanies them.

Erythema is characterised by patches of redness of irregular form, and of rather large size, often somewhat raised above the level of the adjacent skin. When at its height the colour of the patch is vivid red; before disappearing the patch assumes a bluish hue. Pathologically considered, there are two distinct kinds of erythema, one having a local, the other a constitutional origin.

Varieties of erythema of local origin.—When two folds of the skin overlap each other, the secretions accumulate, and the two surfaces chafe each other; inflammation of the skin is the consequence—intertrigo, or erythema intertrigo, as it is called—a disease very common in the groins and necks of young children and fat women. A little moisture exudes from the inflamed surface.

The inflammation of the skin resulting from a burn is one variety of erythema. That peculiar inflammation of the skin which we call a chilblain is, when dignified by a scientific name, erythema pernio. When the skin stretched over an cedematous part inflames, as often happens, the disease is erythema læve. If the patient lies long on one spot, and the skin over it inflames, it is erythema.

Chronic local erythema is pretty common on the face, around the lips, and on the buttocks of young children. The skin, when inflamed about the lips, the orifice of the vagina, the prepuce, the groins, and the anus, is peculiarly liable to crack.

Treatment.—Intertrigo is best treated by frequent ablution, bathing the inflamed surface with an astringent wash—a solution of acetate of lead is one of the best—and then, after carefully drying the part, dusting it with an absorbent powder, such as starch or oxide of zinc. It is important to bear in mind, with reference to erythema læve, that the inflammation of the skin increases the œdema of the subcutaneous tissue. If, as is usually the case, it is the lower extremities which are the seat of erythema læve, they should be raised, to favour not only the return of blood from the limbs, but also the draining of the serosity out of the tissue. A few punctures in the thigh with a fine needle, by permitting the escape of serosity from the cellular tissue, will aid the cure of the erythema. If the œdema be not reduced, bullæ sometimes form on the erythematous surface, and finally the skin ulcerates or even sloughs. As to the erythema from pressure, that is best treated by careful drying of the part after washing, the application several times a day of spirit of wine, or an astringent solution, as alum; but, above all, by extreme attention to cleanliness and frequent change of position. A sore back from pressure rarely occurs in fever or paraplegia, the diseases in which it is most common, if the patient be well nursed.

Varieties of erythema of constitutional origin: *e. fugax*, *e. papulatum*, *e. nodosum*, *e. circinatum* (syn. *annulatum*), *e. tuberculatum*, *e. marginatum*.—The local disease in these varieties of erythema, although characterised by redness, &c., hardly merits the name of inflammation, unless we give to that vague word a very wide signification. All these varieties of erythema are more common in those disposed to rheumatism.

Erythema fugax is distinguished by the sudden appearance of large red patches, and their equally sudden disappearance after a time varying from a few minutes to a few hours. The patches of erythema fugax are more common on the face than elsewhere; not infrequent on the trunk; rather rare on the extremities. The usual cause of erythema fugax is some article of diet. The patches disappear in less than half-an-hour. That erythema fugax results in some cases from nervous influence is rendered probable by such facts as this: a gentleman, known to the writer, cannot even think of eating condiments without experiencing a sensation of heat in the face, forehead, and scalp, conjoined with some redness of the part.

Erythema nodosum is a common affection in girls from six to twelve years of age, and not very rare in delicate boys and adult females, characterised by the eruption of distinctly elevated red patches of an oval, or more rarely circular, form. The oval patches are from one to two inches in length, the circular from half an inch to an inch in diameter. Each patch lasts from four to ten days; fresh patches appearing every day or two. The disease is commonly finished in a fortnight or three weeks. In persons past the middle of life it occasionally lasts for months.

On their first appearance, the colour of the patches is tolerably bright red; but when about to fade, the patches assume a bluish or violet tint. Exposure to cold also gives to the erythematous patch the same hue. This bluish colour is very characteristic of erythema. Over the anterior aspect of the tibia, which is the ordinary seat of erythema nodosum, the patches are commonly oval, their long axis being from above downwards; about the knee-joint, and at the back of the leg, they are usually circular. On the upper extremity, where they appear in rare cases only, they are also circular. They are rarely seen on the lower extremities much above the knee, or on the upper extremities above the elbow. It is very rare for patches to occur on the trunk.

Occasionally, several patches are evolved in the vicinity of each other; and their margins coalescing, a broad red patch is formed, here and there hard, elevated, and very tender, and presenting some resemblance to erysipelas. The redness of erysipelas, however, terminates by a well-defined line; whilst in erythema it shades off into the hue of the adjacent skin. The margin of an erysipelatous patch is as much raised as its centre, the elevation of a patch of erythema nodosum ceases by degrees with the redness. When the finger is passed over a patch of erythema nodosum, it feels as though the hardness were caused by something buried under as well as in the skin. Erysipelatous hardness is brawny in character and superficial. When several patches of erythema nodosum are present, the disease can hardly be confounded with erysipelas. The largest patches of erythema nodosum now and then convey to the finger a sensation of fluctuation; but they never suppurate, and the sensation of fluctuation is probably due to the presence of serosity in the subcutaneous cellular tissue.

Erythema tuberculatum and *papulatum*.—When patches, agreeing in other points with those just described as characteristic of erythema nodosum, do not exceed a four-penny-piece in size, the disease is called erythema tuberculatum; when not larger than a very small split-pea, the disease is called erythema papulatum. Sometimes circumscribed patches of a bright red colour, studded with deeper-coloured points, which to the eye resemble papulae, but are without the elevation and hardness of true papulae, appear on the arms, neck, and breast; the colour and slight elevation are both temporarily removable by the pressure of the finger. To these patches also the term erythema papulatum has been applied.

Erythema circinatum is not a very common disease. It affects children and adults, and ordinarily supervenes in the course of an attack of acute rheumatism. Its usual seat is the trunk.

The patches are ring shaped. Sometimes, however, the rings are imperfect; and not unfrequently several rings coalesce at their margins. The rings are red, distinctly raised, terminate abruptly externally, as regards both colour and elevation, but shade off gradually towards the centre. Within the ring the skin has a faintly yellowish tint. The breadth of the red ring is about one-third of an inch. The patches are quite smooth; there is not a trace of scales, vesicles, or scabs on their surfaces. The colour of the rings of roseola annulata is darker than that of erythema circinatum, the elevation is scarcely perceptible, the outer margin is not abrupt, and the centre is the colour of the natural skin, instead of yellowish. Erythema circinatum, when acute, runs its course in about a fortnight or three weeks. There is a chronic variety, however, in which the rings are incomplete, and to it the name of erythema marginatum has been applied. Willan mentions that it occurs on the extremities and loins of aged persons suffering from internal disorders, and that its occurrence is an unfavourable sign.

Hebra considers *e. tuberculatum*, *papulatum*, *circinatum*, and a species from its form called *gyratum*, to be merely stages of the same species, and for this species proposes the term *erythema multifforme*.

A little desquamation of the cuticle covering the red patches follows the disappearance of all the varieties of erythema and roseola. The eruption of roseola itches slightly; that of erythema usually itches, burns, or tingles in a trifling degree.

It is evident that there is little or no essential difference between roseola and erythema; and that, excluding inflammation of the skin, dependent altogether on local causes, that variety of roseola which so closely resembles measles and erythema nodosum, the other varieties of roseola and erythema might well be grouped together into one genus, and this whether regard be had to their local or general pathology, or to their treatment.

Treatment.—A few warm baths, rest, mild aperients, simple salines, and a light diet, so long as the skin is hot, the pulse quick, and the tongue white; attention to the digestive organs, mineral acids, and vegetable tonics, after the febrile disturbance has ceased—these are the remedies for all. Erythema nodosum, tuberculatum, and

populatum, and the chronic variety of erythema circinatum, usually occur in delicate persons; and in their treatment quinine is said to be particularly useful. Dr. A. Todd Thompson, whose remarks on treatment are always worthy of attention, found bark in many cases much more beneficial than quinine. In women past middle life, the eruption of erythema nodosum is thought to be connected with the cessation of the menstrual discharge. Erythema circinatum occurring in the course of acute rheumatism disappears spontaneously.

Urticaria.—The pathology and ætiology of urticaria, or nettle-rash, are so closely related to erythema fugax, and the two so often occur in the same individual, that we pass naturally from the genus erythema to urticaria. Yet urticaria is not correctly placed among the exanthemata. In urticaria there is something more than redness disappearing or fading on pressure; there are wheals, or pomphi, as they have been called.

Wheals are flat elevated patches of the skin. The sting of a nettle, the bite of a bug, the stroke of a whip, are each followed by a wheal. Wheals differ much in form, size, and colour. In form they may be circular, oval, or irregular; in size, they vary from two lines to some inches in length; in colour, from almost white to deep purple.

In urticaria each wheal is seated on a red patch; sometimes the patch is very large, the wheals small; sometimes the redness forms merely a narrow halo around the wheal; several wheals may be seated on the same red patch. Wheals frequently appear and disappear again with singular rapidity. Now and then the red patches remain for a while after the wheals have vanished; in some cases the red patch precedes the eruption of the wheal, in others the wheal comes out first; while in others, again, they appear simultaneously. When the red patch only is present, the disease may be very readily confounded with erythema; a little friction of the part, however, will prevent the mistake by bringing out the wheal. Now and then the surface covered by the redness is very considerable in extent, and then the wheals not being present, the case might possibly be taken for scarlatina. There may usually be detected on the red parts one or two wheals imperfectly evolved, which will reveal the true nature of the case.

Patients often mistake the pale elevations of the cutis for blebs, and say that large blisters occasionally come out over them. The wheals in urticaria itch, tingle, and burn. These sensations are often almost intolerable. Usually they are aggravated at night when the patient is warm in bed, when seated by a fire, and by the use of stimulating articles of diet. Now and then, however, the wheals and the itching, tingling, and burning sensations are only present when the patient is exposed to cold. Any change of temperature suffices in some cases to determine the evolution of the wheals. The structure of the wheals in urticaria has not been very clearly made out. The redness is, of course, caused by repletion of the vessels of the cutis; but to what is the elevation and pallor of the wheals due? Gustav Simon says that if a needle be passed into the cutis constituting a pale wheal, a little clear serosity only escapes; and he concludes from this that the swelling is occasioned by the presence of serosity in the substance of the cutis. The pallor is attributed to the quantity of serosity effused being out of proportion to the number of vessels loaded with blood. The sudden appearance and disappearance of the wheals seem, however, to be opposed to these ideas.

Urticaria is a very common disease. It occurs at all ages. Persons prone to rheumatism are especially liable to urticaria.

Varieties of urticaria.—Local urticaria results from the application to the skin of certain irritants, e.g. a blow, a sting, &c.

A most acute and severe form of urticaria is not unfrequently the result of a single error in diet. In some persons shell-fish, in others pork, in others pastry, in others the more common articles of diet, as eggs or sugar, produce an attack of urticaria, and this although the food be the best of its kind. In some persons an attack of urticaria only occasionally follows the use of particular substances; in

others it is the invariable consequence. The patient is said to be poisoned by what he has taken. An attack of urticaria having such an origin usually terminates in two or three days. The eruption may appear very rapidly after the ingestion of the noxious substance. It not unfrequently occurs within an hour. The eruption may disappear in a few hours. As a rule, the sooner after the ingestion of the noxious agent the symptoms appear, the more quickly do they disappear. Mr. B. Squire has seen cases of acute urticaria due altogether to the presence of the *acarus scabiei* in the epidermis.

An acute attack of urticaria sometimes occurs without the patient having committed any error in diet. It is then generally preceded for a day or two by some febrile disturbance. There are no special symptoms present in these cases to indicate that the pyrexia is only the prelude of an attack of nettle-rash. The eruption of the wheals is the first intimation of the exact nature of the disease. This variety of urticaria ordinarily lasts a week. It is termed *u. febrilis*.

More frequently urticaria is a chronic disease, and it may then last for years. Sometimes the wheals are confluent, or almost so, and then the disease is called *urticaria conferta*. Occasionally, even in comparatively chronic cases, the wheals that first appear remain out till the patient is permanently well. Urticaria, in which the wheals are thus permanent, is called *urticaria perstans*. Far more commonly the wheals come out in crops, so to say, which last only a few hours, fresh crops appearing with every change of temperature, with every abnormality of diet, or on the slightest friction. Now and then not a wheal appears for a week or two, and then a fresh crop comes out. Urticaria, characterised by these evanescent wheals, is *urticaria evanida*. In rare cases the wheals attain a very large size, and then the disease is *urticaria tuberosa*; in still rarer cases the patient suffers from the burning, itching, and tingling sensations in numerous parts where no wheals appear, and then Willan called the disease *urticaria subcutanea*.

In regard of the species of urticaria, all the important points may be summed up thus: the disease is now and then a very acute disease, distinctly referable to an error in diet; now and then an acute disease not referable to error in diet; more often the disease is chronic, the wheals appearing and disappearing rapidly on the slightest cause, or even without any known cause.

Treatment.—When acute urticaria arises from the patient having eaten some substance which he has imperfectly digested, an emetic, followed by a mercurial and saline aperient, is generally all that is necessary for the cure. If there be much depression at the outset, it may be necessary to give a little ammonia; or, on the other hand, if the febrile disturbance be great, to take a little blood from the arm.

In the treatment of the chronic forms of urticaria especial attention is to be paid to the patient's diet. In some cases abstinence from coffee, in some from tea, in some from milk, in some from porter, in others from the water they were drinking, has been followed by recovery. I know a young lady who always suffers from urticaria when she resides in a particular locality, from the quality, it seems to me, either of the air or of the water at that spot; and she informs me that many persons in the same village suffer from the disease. While residing there, medicine has little effect on the disease; when she leaves that village, no medicine is required for her cure.

After regulating the diet, a mild course of antacid saline aperients is often useful. In other cases, saline aperients, combined with a bitter infusion and a mineral acid, seem to be the most efficacious remedies.

A course of cold sea-baths is sometimes followed by recovery when other means have failed. If the patient is plethoric, and the pulse is full and hard, a single blood-letting, to a moderate extent, affords much relief. In obstinate cases, arsenic in small doses—as three minims of liquor arsenicalis three times a day—continued for some time, has effected a cure. Some physicians attach much importance in the treatment of urticaria to quinine, in doses of two or three grains three times a day. Colchicum is with others a favourite remedy. Carbonate of potash or liquor potassæ, with a bitter infusion, three times a day, is sometimes useful, by correcting deranged conditions of the stomach.

The disease may often be kept in abeyance, the eruption of fresh wheals be prevented, and the irritation of those present be allayed, by sponging the whole surface night and morning with lemon-juice or vinegar. Sir E. Wilson speaks very highly, for the latter purpose, of a lotion composed of bichloride of mercury, from five to ten grains, spirits of rosemary and spirits of wine of each one ounce, and six ounces of the emulsion of bitter almonds.

If a child suffering from urticaria be cutting its teeth, and the gums are hot, dry, and tender, they should be lanced. A single dose of calomel and jalap usually suffices to cure the disease in the young child.

Order 2.—HÆMORRHAGIA.

Purpura is characterised by an eruption of spots (petechiæ) or patches (vibices or ecchymoses), both due to hæmorrhage into the derma, varying in tint from bright red to violet. In diameter they are less than a line to more than an inch; the smallest spots are round, the larger more irregular in shape. At first the spots have an abrupt well-defined margin; but after a time their outline is gradually lost in the surrounding skin. Their distinguishing character is that they do not disappear or fade under pressure, in this respect differing from all forms of eruption with which they could be confounded. In a few days they begin to fade and slowly disappear, becoming orange-coloured and yellowish. New spots appear as old ones die away.

Purpura has been subdivided into *p. simplex* and *p. hæmorrhagica*. The latter is only a severer form of the former, in which hæmorrhage takes place not only into the skin but from the mucous membranes of the nose, alimentary canal, urinary passages, and other parts. Willan described a variety, under the name of *p. urticans*, in which there is a reddish elevation of the skin resembling a wheal, which subsides in a few days, and leaves a livid spot on the level of the skin. *Purpura* is not accompanied with tingling or itching.

In mild cases of *purpura* there is little or no disturbance of the general health. In severer cases, the eruption is often preceded by febrile symptoms, lassitude, and pains in the limbs. In some cases, however, without any previous constitutional disturbance, profuse hæmorrhage may occur both into the skin and from the mucous membranes.

Scorbutus is quite a distinct disease from *purpura*, though, like it, accompanied by cutaneous hæmorrhage. The gums are not spongy in *purpura*, nor is there usually the yellow sallow hue which is met with in scurvy. Some of the acute specific diseases are occasionally accompanied with petechiæ, and typhus is specially called the petechial fever from the ordinary characters of its eruption. Other symptoms will enable the practitioner easily to distinguish these eruptions from *purpura*. Neither the pathology nor the ætiology of *purpura* is understood. It is not dependent on a want of fibrin in the blood, nor is it caused by the want of fresh vegetables, or even by poor living.

Treatment.—Astringents, such as gallic acid and acetate of lead, are occasionally of use. The tincture of the sesquichloride of iron and mineral acids have been useful in other cases. Turpentine and creasote have been much extolled by some writers. Dr. Williams thinks that *purpura* is often connected with hepatic congestion and imperfect secretion of bile, and is best treated by remedies which tend to relieve this state.

T. H.

Order 3.—VESICULÆ.

Sudamina.—The vesicles to which this term is applied resemble minute drops of perspiration. They are colourless and very transparent. There is no redness around them. Sometimes they are so small that they are more easily detected by the finger than by the eye. In two or three days the vesicles either burst, or the fluid in them disappears, and there is a little furfuraceous desquamation of the cuticle at the parts where they were situated. The contents of a sudamen never become opalescent.

Sudamina appear in the course of certain acute and chronic affections, and are especially common in typhoid fever, during the third week of the disease. A single crop of sudamina never lasts more than two or three days. I think, in common with others, that these vesicles are seated at the orifices of the sweat-ducts, and that they are connected with the occurrence of perspiration. They may cover the whole anterior and lateral regions of the trunk; but more commonly they occupy those parts to which perspiration is often limited, *e.g.* the base of the neck, the sides of the thorax, the epigastrium, and the groins.

The contents of the vesicles are almost always acid. Sudamina rarely occur after the middle period of life. They are of no value as a guide for prognosis; and as to treatment, they themselves require none. A crop of sudamina indicates that the patient has perspired, and should lead to inquiries into the ventilation and temperature of the room, the condition of the linen of the patient, &c.

Miliaria.—Miliary vesicles are acuminated with a red halo around their bases. Their contents quickly lose their transparency, and become almost or quite purulent in appearance. Miliary vesicles occur, like sudamina, in the course of other affections. They are often seen on the trunk and extremities in acute rheumatism. They differ from sudamina in being acuminated, in the opacity of their contents soon after their eruption, and in the redness of the skin around.

Like sudamina, they appear to be connected with the occurrence of perspiration. During the summer months it is very common to see the trunk of children, and even of adults, who perspire freely from exercise or other cause, and especially if they are not frequently washed, covered with a crop of minute miliary vesicles. In these cases the redness around each vesicle is sometimes much more readily seen than the vesicles themselves, and then the disease may be mistaken for *roseola æstiva*. Not unfrequently *roseola æstiva* is complicated with the eruption of a few miliary vesicles.

Frequent ablution and a gentle purge are all that is required in the treatment of the miliary vesicular eruption of children. There is an epidemic febrile disease of from eight to ten days' duration, characterised by profuse sweating and a miliary eruption. It has been called miliary fever; some cases of it are detailed in Rayer's work on skin diseases. Some persons under the term miliary vesicles include sudamina and miliary vesicles proper.

Eczema is a very common disease, and occurs at all ages. It is characterised by the eruption of small vesicles on imperfectly defined patches of skin of some extent. The vesicles are usually pretty thickly set. Each vesicle is surrounded by more or less inflammatory redness. Sometimes the redness around the vesicles is scarcely perceptible, sometimes the whole skin between them is uniformly red, hot, and swollen; in the latter case, however, detached vesicles are always to be found at the margins of the patches, each having its areola of redness. When the vesicles burst, thin scales or scabs cover the surface of the patches. These scales or scabs are composed of epithelium, and the fixed constituents of the fluid of the vesicles. When the fluid in the vesicles contains but little animal matter, the scales are thin, white, and opaque, and the disease may be mistaken for one of those belonging to the order squamæ.

When the fluid of the vesicles contains much animal matter, the scabs are brownish or yellowish in hue. But the scabs formed from the drying up of a crop of the vesicles of uncomplicated eczema are never thick. The disease may disappear with the drying up of the first crop of vesicles; but this is by no means constantly the case. Two, three, or more crops of vesicles may follow each other in quick succession; and the surface on which they are seated may be red and raw in appearance, and a clear serous fluid, strongly alkaline in reaction, ooze from it in considerable quantity. This fluid excites inflammation of the surface over which it flows. It scalds, as it is said. Instead of being raw in appearance, it may be that the surface is hot, red, and swollen; and just under the cuticle are perfectly flat irregularly-shaped collections of serosity, or of somewhat purulent-looking fluid. The appear-

ance is as if turbid serosity or thin pus were burrowing in all directions just under the epidermis. The fluid in this, as in other forms of eczema, is alkaline. Scabs of large extent, but still thin, are formed by the drying up of this subcuticular fluid.

Where the cuticle is rather thick, and the vesicles are very small, the surface may seem to be red and rough only, with cracks here and there, from which a more or less alkaline serosity oozes in small quantity. The surface thus affected is often of considerable extent. It is a common form of eczema on the anterior aspect of the leg in persons past the middle period of life. The urine of those who suffer from it often contains a large quantity of the crystals of oxalate of lime.

Vesicles are not, according to Hebra, constantly present in eczema, and he therefore defines eczema as follows: 'A disease of usually chronic course, characterised by the formation of aggregated papules (e. papulosum) and vesicles (e. vesiculosum) or by more or less deeply red patches covered with thin scales (e. squamosum), or in other cases by a moist surface (e. rubrum); while in any of these forms there may be developed in addition, partly yellow and gummy, partly green or brown crusts (e. impetiginosum). The affection is constantly accompanied by violent itching which leads to excoriations, and it is not contagious.' 'I do not consider the formation of vesicles, and subsequently of a moist surface, as sufficient to characterise the disease; but take in as varieties of the same malady all the morbid changes seen in the course of development and retrogression of the ordinary vesicular and moist eczema.'

The eczema papulosum is, Hebra states, the lichen eczematoïdes, and eczema squamosum the pityriasis rubra of some writers.¹

Varieties of eczema. - As to the nominal varieties of eczema, the disease is called eczema vulgare or simplex, when the vesicles are distinct from each other, though pretty closely crowded, last a few days only, and then dry up and form furfuraceous scales. The inflammation of the cutis in e. simplex is never very severe, and may be trifling. E. simplex may be excited by any direct irritant of the skin; as, for example, a stimulating liniment, exposure to the direct rays of the sun or of a strong fire, sugar, sulphur.

Eczema rubrum is distinguished from e. simplex by the degree of inflammation that accompanies the eruption; the cutis between the vesicles is uniformly inflamed, eczema simplex may therefore pass into eczema rubrum. In eczema rubrum the cutaneous and subcutaneous tissues are often considerably swollen; the swelling is for the most part due to the effusion of serosity.

There are two diseased states of the skin called by the common name of eczema impetiginodes. In one, the inflammation is very severe, and the secretion is here and there purulent; in the other, eczema is complicated with impetigo, i.e. with suppurative inflammation of the hair-follicles.

Hebra has described a variety of eczema which he terms eczema marginatum. It is almost limited to males, and especially observed in shoemakers. Its most constant point of origin is on the inner part of the thigh, with which the scrotum comes most in contact, and thence it may spread upwards to the abdomen, leaving untouched the penis and scrotum. Subsequently the disease may appear on other parts, e.g. breast, back, neck, extremities.

This variety of eczema begins, Hebra states, as a red, raised circular patch of the size of a sixpence; it spreads at the periphery and there occur in succession papules, vesicles, excoriations, and afterwards small brown or black scales. As the circumference spreads, the centre heals, but retains a dark colour. Subsequently similar patches may appear in other regions. Although Hebra denies the syphilitic nature of this form of eczema, other writers are disposed to question his conclusion.

The face, the hairy scalp, and the skin behind the ears are all common seats of eczema; but there is no part of the trunk or extremities which it may not, nay does not, frequently affect.

Before and during the period of the first dentition, eczema is by far the most common of the diseases of the scalp. If a single crop of vesicles only appears, the disease will run its course in a week or ten days; but if crop after crop of vesicles follows each other, or if the surface is highly inflamed and 'weeps,' the disease may continue for a considerable length of time. When very obstinate, lasting for years, it has been called eczema inveteratum. Strumous children, from five to twelve years of age, are very liable to eczema of an obstinate character at the flexures of the elbow and knee-joints. An acute attack of eczema is sometimes preceded for a day or two by tolerably severe febrile disturbance. There is nothing characteristic, however, in the febrile symptoms; but the patient who has had one attack, being very liable to others, may suspect its nature. Sometimes, too, he feels before the eruption appears a peculiar heat and tingling of the part about to be the seat of eruption.

Parts affected with eczema burn, tingle, and itch. Some varieties of eczema are attended with intolerable itching; for example, eczema of the anus, labia pudendi, and scrotum, especially in old men, whose urine dribbling away irritates that part. Eczema is not contagious.

In children, as a rule, eczema is secondary to some constitutional state. In adult age it is more commonly due to direct irritation, as about the vulva in saccharine diabetes. In females it now and then appears in connection with derangement of the catamenial function, without known local exciting cause. Eczema of the lower extremities is sometimes secondary to a varicose condition of the veins.

Treatment.—The treatment of an acute attack of eczema must be influenced by the severity of the local affection, the presence of febrile disturbance, and the age and strength of the patient.

If the disease be acute, the local affection extensive, and accompanied by a good deal of heat, redness, and swelling, and the patient in the prime of life and robust, the best treatment is to take a moderate quantity of blood from the arm, to give a brisk calomel-and-colocynth purge, to follow this by a saline, antacid aperient, and to bathe the part itself with tepid goulard water. After the bowels have been freely acted on, small doses of antimony may be given every three or four hours. The diet in such cases should be low. If the patient be less robust, then the blood-letting must be omitted, and the purging and other treatment less active.

If the disease be chronic, and the inflammation moderate in degree, a bitter acid aperient, such as sulphate of magnesia one drachm, dilute sulphuric acid 10 drops, infusion of gentian $1\frac{1}{2}$ ounce, two or three times a day, is often very useful. Young children require occasionally a calomel-and-jalap aperient at bedtime. In the chronic forms care must be taken to ascertain that the patient is committing no error in diet. It is only in the aged or the delicate that stimulants, as wine or beer, are admissible. Slightly astringent local applications, as zinc ointment, are the best for mild cases. If the disease is very chronic, and there is little heat of the part, stronger local means are required, such as an ointment composed of half a drachm of the hypochloride of sulphur to one ounce of simple cerate, or a scruple of iodide of sulphur to half an ounce of simple cerate. In the strumous variety above mentioned as so common at the bends of the elbows and knees, and in that in which the cuticle is rough and cracked, and there is serous fluid oozing from the surface, a piece of linen soaked in a solution of nitrate of silver, a scruple to an ounce of water, may be applied twice a day. When, in the last-mentioned form, the urine contains a large quantity of oxalate-of-lime crystals, the nitro-muriatic acid, with decoction of bark and a good diet, should be prescribed. In strumous children, cod-liver oil and a good diet are essential to the cure. When young children suffer from eczema of the scalp, and the gums are hot, dry, and swollen, they must be lanced. If the disease continue, and the inflammation do not involve the cellular tissue, I have seen the disease rapidly yield to the plan of treatment recommended by Hebra:—The hair being cut off by a fine pair of scissors, and the scabs removed by linseed-meal or bread-and-water poultices, linseed-oil is to be applied at bedtime to the whole scalp, and the following morning the part is to be covered with liquid pitch; a single application is sometimes sufficient for the cure; when the pitch peels off, the scalp is found free

from eruption or inflammation. Care must be taken not to employ so stimulating an application as liquid pitch when there is much heat and swelling of the part. A child in the Hospital for Sick Children was nearly killed under such circumstances by the inflammation set up by the pitch; the inflammation extended from the scalp down the neck, and even below the clavicles, and abscesses of some size formed in the cellular tissue of the inflamed parts. However, when the child recovered from the terrible disease excited by the pitch, it was free from the eczema, and its cure was permanent, notwithstanding that it had been suffering from the affection of the scalp for two years previously. In very obstinate cases, in children as well as adults, arsenic administered internally exerts a decidedly favourable influence; three or four minims of the liquor arsenicalis in a little water twice a day to an adult, and a single minim to a child.

Parts affected with eczema should be washed frequently. Strong soaps should not be employed. Some physicians recommend the patient to use a little bran-water only; others employ egg instead of soap for washing the part. It is desirable to prevent the secretion from the inflamed surface running over the adjacent healthy skin; therefore the part should very frequently be wiped gently with a piece of soft lint. Dr. H. Bennet speaks in very high terms of the advantage he has seen follow from keeping the part constantly wet with a solution of subcarbonate of soda, two drachms to a pint and half of water. To prevent the lint drying, it is necessary to cover it with oil-silk or gutta-percha. The constant application of cold water is strongly recommended by Hebra; over the water a caoutchouc bag containing ice may be applied. He also after removing crusts employs various caustic applications, especially caustic potash, in form of solution or of soap.

The treatment of eczema may be thus summed up. If the local affection be manifestly inflammatory, it must first be treated altogether independently of the special eruption. When the active inflammatory stage has passed by, stimulating astringents must be applied locally, and the constitutional derangements treated as though there was no local affection; and lastly, these means failing, those remedies must be employed which may be denominated empirical. Always bearing in mind the importance of a diet regulated according to the age and general powers of the patient, and the necessity for local cleanliness.

Herpes is, like eczema, a non-contagious vesicular disease very common at all ages. It differs from eczema, however, in several particulars. The vesicles are arranged in groups on small, or at least not very large, pretty well-defined and somewhat elevated red patches. The vesicles of eczema are always small; those of herpes usually of some size.

The fluid of the vesicles is at first quite transparent, but it soon grows opalescent or puriform, and after a short time the fluid and the epidermic covering of the vesicles concrete into thin pale brownish scabs. When quite transparent, the fluid of the vesicles is slightly alkaline or neutral to test-paper; when opalescent, neutral or acid. The fluid of the vesicles in herpes never has the strongly alkaline reaction so remarkable in the transparent fluid that 'weeps' from the red surface of a patch of eczema.

Varieties of herpes.—The red slightly elevated patch that so often forms on the lip during that little feverish attack commonly called a cold, and which is shortly after covered by a crop of vesicles, is *h. labialis*. In a day or two the vesicles are replaced by a thin brownish scab; in two or three days more the scab falls off and a red stain only remains. When such an eruption occurs on the prepuce, as it often does, it is *herpes præputialis*. Patches identical with these, except that they are broader, and that the vesicles on them are larger, may appear on any part of the body, constituting *herpes phlyctenodes*. The cheek is a common seat of *herpes phlyctenodes*. Several patches often appear in the vicinity of each other. The disease ceases, as a rule, in less than a fortnight. Sometimes a week suffices for it to run its course.

Herpes zoster, zona, or shingles, as it is vulgarly called, is distinguished from the other varieties of herpes by the number and position of the patches of vesicles.

Several patches, distinctly separated from each other, appear at the same time or in succession. These patches are usually oval, and arranged on a line passing somewhat obliquely downwards and forwards from the spine to the middle line, in front. Most commonly they are seated on the thorax, next on the abdomen, and rarely on the face and neck. The patient is usually poorly for two or three days before the vesicular patches show themselves; sometimes considerable febrile disturbance precedes the eruption, and occasionally the patient suffers severe burning pain in the part where the eruption is about to appear, and even deep-seated pain in the chest when the thoracic parietes are to be its seat. *H. zoster* rarely occurs on the two sides of the body, and still more rarely is it symmetrical.

At first the contents of the vesicles are transparent, then turbid, and then thin brownish scabs follow. The disease runs its course in ten days or a fortnight. In rare cases, and only in adults, after the scabs fall off, the part on which they were seated is the seat of very severe and long-continued neuralgic pain.

Herpes zoster affects young children more frequently than it does adults. No age, however, is exempt. It rarely occurs twice in the same individual. In children and young adults it is a disease, medically speaking, of little moment.

As to the pathology of herpes zoster, the eruption is secondary to a general febrile affection, and the seat of the eruption is determined by the distribution of particular nerves, and most commonly of the dorsal nerves. The pain that precedes the redness, the limitation of the disease to one-half the body, the frequency with which it follows the course of some of the nerves on the thorax and abdomen, and even the fact that in some cases the upper arm has formed, so to say, part of the semicircle—all point to this conclusion. In reference to these last facts it may be observed that the lower intercostal nerves supply cutaneous branches to the abdominal integument, and that the second dorsal nerve supplies a branch to the skin of the upper arm, viz. the intercosto-humeral. When on the face, it follows the distribution of the fifth nerve, usually one division only; I have seen many cases of two divisions affected. Mr. Hutchinson has observed iritis complicate herpes following the course of the ophthalmic division of the fifth nerve. Theoretical consideration led Von Baresprung to regard the primary lesion to be irritation of the ganglia on the posterior roots of the nerves; the disturbance of the contiguous sensory fibres producing the neuralgia. Subsequent anatomical examinations have to some degree confirmed this view of the exact pathology of herpes zoster.

Treatment.—A mild aperient and a simple saline only are needed. No local treatment is required; nay, local applications very often seem to do harm: troublesome ulcers often follow the application of the most simple dressings. Herpes zoster is an acute disease, having a definite course and duration; a disease that, if let alone, is sure to get well, supposing the patient not to be very old or infirm. But the vulgar have an idea that, if the disease pass round the body, death from it is certain; and in some parts of the country the poor regard it as a most serious disease. Gangrene of the parts affected in very rare cases follows in infirm aged persons.

The neuralgia which now and then occurs as a sequel to the eruption is best treated by local anæsthetics, as belladonna or chloroform. Not unfrequently it resists all treatment.

Herpes iris is a very rare variety. Each patch is about the size of a sixpence, and constituted by three or four concentric rings of different shades of red. On these rings the vesicles are situated; a solitary vesicle occupies the centre. Willan states that the back of the hand is the most common seat of herpes iris; that it is not connected with any perceptible constitutional disorder; that it disappears spontaneously; and that it is limited to young persons.

Herpes circinatus occurs at all ages. The breadth of the red ring in herpes circinatus varies from a line to a third of an inch; the diameter of the ring from a quarter to two inches; the size of the vesicles from the smallest perceptible by the eye to almost as large as the half of a small split-pea.

When the vesicles are of large size, they undergo the same changes which vesicles of herpes zoster experience; that is to say, at first the fluid in the vesicles is trans-

parent, then turbid, and then the walls of the vesicles and their contents dry up into brownish scabs. A second crop of vesicles may follow; but the disease usually runs its course in a week or ten days. Sometimes several patches of the same kind appear in succession on various parts, and thus the disease may be prolonged for some little time.

As to the treatment of herpes circinatus with large vesicles, a gentle aperient, rest, and a light diet only are required.

That variety of herpes circinatus in which the vesicles are very small is by far the most common and the most important. It is the *ringworm* of the face, trunk, and extremities. From the frequency with which minute scales are found on the red ring, it may be called the furfuraceous variety of herpes circinatus, and to this variety only the following remarks apply.

Herpes circinatus commences as a red spot; and the annular shape is the result of the extension of the inflammation at the margin of the spot, while the centre regains its healthy aspect. It is one of the centrifugal affections of the skin. Occasionally a second, a third, and even a fourth ring is seen within or without the primary circle. Every now and then we meet with cases in which the centre of the ring, instead of regaining its healthy structure as the margin extends, is the seat of repeated eruptions of very minute vesicles, and so has a rough, rather scaly, appearance. This latter form is especially common in strumous children, whose skin is naturally rough. It is peculiarly chronic in its course.

The furfuraceous variety of herpes circinatus is a purely local affection. In this it differs from most of the other species of herpes. In herpes zoster, h. phlyctænodes, and h. labialis, the eruption is preceded by, and is altogether secondary to, a general febrile state. The local affection in these diseases bears the same sort of relation to the general state that the rash of measles bears to the general state that precedes its eruption. Herpes circinatus is not secondary to, or even accompanied by, any constitutional derangement. It differs in another particular from most of the varieties previously described. They are acute diseases; it may be a chronic affection. Each crop of vesicles runs, it is true, an acute course; but repeated crops often give to the disease a chronic character. The furfuraceous variety of herpes circinatus may by the inexperienced student be confounded with roseola annulata, erythema circinatum, psoriasis vulgaris, lichen circumscriptus, and tinea tonsurans. In psoriasis, the elevation of the red ring is greater than in herpes circinatus, and the scales form the prominent feature of the local disease, instead of requiring to be looked for, as in herpes circinatus. There are no elevation of the skin, no vesicles, and no scales in roseola annulata. The abrupt outer margin, the breadth of the ring, the yellowish tint of the centre, and the absence of vesicles and scales, distinguish erythema circinatum. Lichen is a papular disease.

Treatment.—Topical applications only are required for the cure of the furfuraceous variety of herpes circinatus. Local astringents and stimulants are the remedies. The vulgar apply ink, and cure many cases by it. A concentrated solution of sulphate of iron answers well in some cases; so also does a saturated solution of gallic acid. A single application of strong acetic acid, or of a strong solution of nitrate of silver (a drachm to the ounce of distilled water), or of blister-fluid, will occasionally suffice to remove a patch of herpes circinatus which has resisted less powerful agents. This furfuraceous variety of herpes circinatus is contagious. It is almost limited to the young, and is far more common in childhood than in early adult age. In and by itself herpes circinatus is a trifling affection; but considered in reference to the relation it bears to the development of the vegetable parasites, it is a very important disease.

Order 4.—BULLÆ.

There are two genera of the diseases of the skin characterised by an eruption of bullæ or blebs, viz. pemphigus or pompholyx, and rupia.

Pemphigus is not an uncommon disease. The bullæ are very perfect. In size they vary from that of a split-pea to half an egg; the larger are not formed by the

coalescence of the smaller. If there be any red margin to the bullæ, it is very narrow; often there is no redness around. In some cases the bullæ are preceded by a red spot of the same size as the coming bleb; the bulla itself having its full circumference from the first, only being less elevated than it becomes in its progress. Sometimes, however, a vesicle appears, and the bulla is formed by its extension in all directions. At first the bulla is transparent; subsequently the fluid becomes opalescent and frequently puriform; at the same time, or it may be before the fluid loses its transparency, the cuticle covering it grows opaque. In the latter case the bulla looks as though it were filled with puriform fluid, and it is only by puncturing it that the chief cause of the opacity is discovered. In cachectic and aged persons the fluid is often sanguinolent.

The fluid of the bullæ in pemphigus resembles the serum of the blood in chemical composition. It is faintly alkaline or neutral so long as it is transparent; when it becomes puriform, it is acid. After attaining its full size the bulla bursts, then the cuticle covering it falls into folds or wrinkles, and, with such portion of the contents as has not escaped, dries and forms a scab. A few days only elapse from the eruption of the bulla to the formation of the scab. The scab or crust varies in thickness; usually it is thin, sometimes foliaceous, never very thick. After a time the scab falls off and leaves a reddish stain or scar, not a cicatrix. Now and then, when the scab is detached, a superficial ulcer is exposed. If the bleb be broken, and the cuticle removed, the surface is excoriated.

In rare cases only one bulla is present at the same time; bulla after bulla on different parts of the surface following each other in succession. This is the pemphigus solitarius of Willan. Usually there are many bullæ present at the same time, and they are either scattered or grouped. When many are seated near to each other, the skin between is usually red, and the lymphatic glands to which the lymphatics of the part lead enlarged and tender. This affection of the glands is out of proportion to the inflammation about the bullæ. The glands rarely, if ever, suppurate. The bullæ of pemphigus are more common on the extremities than elsewhere; but they are often seen on the trunk, genital organs, and face; less frequently on the hairy scalp. Rayer and A. T. Thompson say they have seen bullæ in the mouth and on the velum palati. There seems to be no foundation for the assertion that they are found on the gastro-intestinal mucous membrane.

When present on the soles of the feet or palms of the hands of infants, they are evidence of constitutional syphilis. Pains and heat of the part accompany the development of the bullæ.

Varieties.—1. Pemphigus may occur as an acute disease in young subjects otherwise healthy. The eruption is preceded for two or three days, and is accompanied, by febrile disorder more or less decided. Under these circumstances, the disease runs a course of from one to four weeks. When prolonged for a month, two or three crops of bullæ follow each other; when over in a week, the disease ends with the scabbing of the first eruption.

The occurrence of idiopathic acute febrile pemphigus has been denied by some writers. 'That there is indeed such febris bullosa cannot henceforth well be doubted. Still Rayer's observation, that it is a rare disease, appears correct, since many physicians of large experience have never seen a case, e.g. Hebra. I also have never witnessed the acute form.'¹ The writer of this article has seen one case.

2. Persons of damaged health and old people also suffer from a severe febrile form of pemphigus, which runs a quick course.

3. More commonly, pemphigus occurs as a chronic disease, lasting months or even years. This form of the disease is seen in persons of average health, in the cachectic, and at all ages, from childhood to extreme old age. It is unaccompanied by febrile symptoms; but as the chronic course the disease runs depends not on the duration of individual bullæ, but on the repeated eruption of new bullæ, we observe, when they come out in crops, that a little headache, sense of languor and malaise, and trifling febrile disturbance, precede the eruption.

¹ Gustav Simon, *Die Hautkrankheiten*, p. 194

Synonyms.—The names given by writers to the above varieties are founded, 1st, on the duration of the disease: acute pemphigus, febris bullosa, chronic pemphigus, pemphigus diutinus; 2nd, on the presence or absence of febrile symptoms: pompholyx pyreticus, pompholyx apyreticus; 3rd, on the degree of severity of the general disease: pemphigus benignus; 4th, on the number of the blebs and their arrangement: pemphigus solitarius, pemphigus en groupes.

Nature and seat.—The local affection in pemphigus is secondary to some constitutional or general condition. This is especially clear in the acute febrile variety; for in that form well-marked and sometimes very severe pyrexial symptoms, headache, and languor precede the eruption for two or three days. No doubt certain other symptoms are the direct consequences of the local affection; *e.g.* irritation from sleeplessness, derangement of the digestive organs. Of the nature of the general disease to which the local affection is secondary, we know no more than we know of the nature of the fever which precedes the eruption of small-pox. The fluid of the bullæ is poured out from the surface of the true skin, and collects under the epidermis. There is no evidence to show that the bullæ originate in any of the special structures of the skin.

The lesions found after death have been various evidences of inflammation of the intestinal and urinary mucous membranes, and in almost every case fatty liver.

Prognosis.—Pemphigus is always a grave affection. To the cachectic and aged it is often fatal. As a chronic disease it is most obstinate.

Diagnosis.—Varicella, herpes zoster, and rupia are the diseases said to resemble pemphigus. But there is little danger of confounding it with any other disease when the bullæ are present; their large size, the small amount of inflammation around them, the absence of anything which can be called a base, and their irregular distribution, are peculiarities which permit no mistake in diagnosis. The fever which in rare cases precedes their eruption has no diagnostic characters.

Cause.—Of the causes of pemphigus very little is known. Mental distress, exposure to wet—*e.g.* prolonged stay in water—and derangements of the urinary organs, have all been considered to be predisposing causes. Attempts have been made several times, without effect, to communicate the disease by inoculation of the fluid from the bullæ. Scharlan, however, succeeded in producing bullæ by inoculating himself from an infant four days old suffering from pemphigus. The child appears to have communicated the disease to several persons.¹ In this case the disease was probably of syphilitic origin. Febris bullosa, as acute pemphigus was formerly called, is said to have occurred as an epidemic, and then to have spread by contagion.

Treatment. Local.—Directly a bulla is detected, the cuticle covering it should be punctured with a fine needle. This stays its increase in size. Care must be taken to prevent the cuticle being rubbed off, as the surface exposed will be excoriated, painful, and tender. Dr. A. Todd Thompson recommends that the parts, after the escape of the contents of the bulla, should be pencilled with a solution of nitrate of silver, in the proportion of a drachm to a fluid ounce of water, acidulated with ten or twelve minims of dilute nitric acid. This solution hardens the cuticle and forms a good covering, he says, to the tender surface beneath it. All other local means are useless until scabs form; and then, if these are thick, and several are in juxtaposition, with the skin beneath ulcerated, a poultice of bread and water may be applied with advantage. If the ulcers do not heal after the separation of the crusts, they may be stimulated by nitrate of silver.

The general treatment varies with the state of the constitutional disturbance and the general powers of the patient. If the patient be a strong young adult of temperate habits, the pulse full and hard, and the febrile disturbance considerable, benefit will follow abstraction of blood from a vein; but cases requiring, or even permitting, blood-letting are rare. Rest, mild aperients, and spare diet are usually sufficient, even in the acute febrile form, to bring the case to a successful termination.

¹ Caspar, *Wochenschrift für die gesammte Heilkunde*, p. 186, 1841.

When the disease occurs, as is more common, in the aged or the cachectic, bark and ammonia, quinine and the mineral acids, and generous diet, with a moderate supply of alcoholic stimulants, are indicated. Opiates at bedtime are frequently required.

In the chronic apyrexial form the treatment must be regulated by the general state of the patient.

Arsenic exerts little or no influence. (Mr. Hutchinson, however, and many others, regard it as an almost unfailing remedy.) Iodide of potassium is of use only when the disease is of syphilitic origin. Cod-liver oil is sometimes beneficial. Tepid baths have been of service; but occasionally fresh crops of bullæ have followed directly on their employment. If tepid baths are taken, gelatine should be dissolved in the water. Alkaline baths have been recommended for allaying the irritation of the surface. When successive crops of bullæ occur on the same part, the skin at the moment it is free from eruption may be painted with a solution of nitrate of silver sufficiently strong to blacken the surface.

A milk diet has sometimes succeeded when other means have been useless. Cazenave says that he has often obtained good results from giving the patient acorn-coffee.

A case was some time since under the care of the author which resisted all remedies. The child would appear to be nearly well, and then again a new crop made him as bad an object as before. When admitted into the Hospital for Sick Children he had already been suffering for more than two years, and had been into more than one hospital, and under the care of several private practitioners, the parents being well-to-do in the world. He took measles while in the hospital, and from that time was free from pemphigus. There was no return of the affection for a year, *i.e.* when the last report of him was received.

Rupia.—The bullæ in *rupia* are small and somewhat flattened; their contents very soon become opaque, and are not unfrequently sanguinolent. They are seated on a *very* slightly raised base, and are surrounded by a distinct inflammatory flush. A thick dark-coloured rough scab or crust is formed by the drying up of the bullæ. If not forcibly removed, the scab remains attached for a considerable time. An ulcer, often deep and intractable, is exposed on the removal of the scab.

Sometimes the ulceration extends beyond the margin of the first scab before it is detached, and then a scab forms under the primary one, and of larger circumference; and this process is repeated until a conical crust, of considerable thickness in the centre, and an inch or more in diameter, is constituted. This crust is commonly and aptly compared to a limpet-shell. This variety of *rupia* is called *r. prominens*. It is evidence of a profound constitutional cachexia, in the majority of cases, if not in all, of syphilitic origin.

In other cases of *rupia* the ulceration is the marked feature. The scab is imperfect, and when detached an unhealthy-looking and spreading ulcer is exposed. This is *r. escharotica*. Sloughs occasionally form on the floor and at the margin of those ulcers; and then the disease has been mistaken for pemphigus, and called *p. gangrænosus*. In *rupia simplex* the crusts are of moderate thickness, and the ulcer which follows is neither deep, nor does it exhibit any tendency to spread. Neither scab nor ulcer is remarkable. Hebra holds that *r. simplex* always precedes *r. prominens*, *i.e.* that the latter is but an advanced stage of the former; and G. Simon thinks he is right. In fact there is no line of demarcation to be drawn between the varieties of *rupia*. The one passes by insensible degrees into the other.

Rupia is a chronic disease, and is usually limited to the limbs and loins. It is not contagious, and is almost limited to persons of damaged health. It is common in the cachectic state of the system which so often follows the acute specific diseases. *Purpura hæmorrhagica* is an occasional complication. *Rupia prominens* is frequent in the advanced stages of constitutional syphilis. *R. simplex* is common in children of six or seven years of age. *R. escharotica* and *gangrænosus* are limited to young children; the two latter are rare diseases. It is not known what special structure of the skin is primarily affected in *rupia*.

Rupia is more like to ecthyma than to any other disease of the skin. In ecthyma

there are pustules; in rupia bullæ; but then the serum of the bullæ is soon replaced by a puriform fluid. The red base of rupia is much less raised and decided than that of ecthyma; the scab is thicker and not imbedded, and the ulceration following the scab is greater.

Treatment. Local.—The bullæ of rupia should be punctured as soon as they arise. When scabs are formed, they should be removed, and the ulcers dressed with some slightly-stimulating application. A solution of nitrate of silver is frequently of much benefit.

General—The subjects of rupia are always cachectic or debilitated. Tonics, especially quinine, are indicated. Decoction of cinchona, with mineral acids, will sometimes agree with the patient when quinine will not. The tincture of *serpentaria* is sometimes very useful in rupia. The diet should be generous. Wine is generally required, and is borne well even by children.

Order 5.—PUSTULÆ.

Impetigo,¹ one of the most common of the diseases of the skin, is characterised by an eruption of small pustules, followed by thick rough crusts. The pustules of impetigo are of two kinds; the one pale yellow, flat or rounded on the surface, very slightly elevated above the cutis, and having comparatively little redness around; the other very small, acuminate, and having a red and somewhat elevated base, disproportionately large in comparison with the suppurating points. The latter are *achores*, the former *pydracia*. *Achores* are common on the face of children; *pydracia* on the scalp and other parts covered by long hair.

The pustules of impetigo are sometimes scattered at a distance from each other, sometimes grouped into clusters on a red ground; and the red ground in the latter case may precede the eruption of the pustules, as it does the eruption of the vesicles in herpes.

The crusts that follow the pustules are always thick; those that succeed to the *achores* are transparent and tenacious, and resemble in appearance inspissated honey and some kinds of gum; those that succeed the *pydracia* are either small, separate, and dry, or, covering some extent of the surface, are thick, rough on the surface, and particularly solid.

The lymphatic glands, to which the lymphatics of the part lead, are invariably enlarged in impetigo. This enlargement of the lymphatic glands is not limited to those cases in which there is a considerable amount of inflammation or a copious eruption. A child brought to the physician because of the enlargement of one or more of the lymphatic glands of the neck will frequently be found to have an unsuspected spot or two of impetigo of the scalp. The *achores* and *pydracia* are alike accompanied by this glandular affection.

In very exceptional cases the suppurative inflammation destroys the root of a few of the hairs, and thus a very small bald spot remains after the crusts have separated. In the vast majority of cases not one of the roots of the hairs is destroyed. A certain amount of itching frequently accompanies impetigo; in extremely rare cases the pustules are exquisitely painful to the touch, and in still rarer cases intractable ulceration follows the separation of each crust.

The pustules characteristic of impetigo are produced by inflammation of the hair-follicles, terminating in suppuration. Impetigo is thus anatomically and pathologically defined as suppurative inflammation of the hair-follicles. The difference between *achores* and *pydracia* is probably due to anatomical differences of the hair-follicles of the face and those of the perfect hair-producing parts, or on the relative proportions of the hair-forming follicle proper and of the sebaceous structures which enter into the composition of the perfect hair-follicle. On the hairy scalp the *achores*

¹ Hebra considers all cases of impetigo, excepting impetigo *sparsa* of the extremities, to be forms of impetiginous eczema. The glandular enlargement is sufficient in many cases, however, to distinguish them, as is the strongly alkaline reaction of the fluid in all varieties of eczema.

are almost limited to the occipital region, and especially to that part corresponding to the interval between the insertion of the muscles.

Achores are far more common in the child than in the adult.

The admitted varieties of impetigo are due—to the seat of disease (thus we have *i. faciei* and *i. capitis*); to the close approximation of the pustules on a defined inflamed surface, or to their being scattered at a distance from each other, the space between being pale (these differences have given origin to the names *i. figurata* and *i. sparsa*); to the character of the inflammation which precedes and accompanies the acute development of the pustules of certain cases of *i. figurata* (hence the variety *i. erysipelatoides*); to the thickness and extent of the crust which follows (when the face is covered by a thick crust, the variety is *i. larvalis*; when a thick crust covers a large surface of an extremity, it is *i. scabida*—this latter is limited to adults: ‘In the lower extremities,’ Bateman observes, ‘the disease is most severe and obstinate; is ultimately conjoined with anasarca, and often produces severe ulceration;’¹ when the crusts are small, dry, and adhere for some time to the hair after they have separated spontaneously from the cutis, the disease is termed *i. granulata*); to intractable ulceration following the pustules (it is doubtful, as has been suggested by ‘Azenave, whether *i. rodens*, as this variety is named, would not more correctly be placed as a species of *lupus*); to the duration of the disease, *e.g.* *i. acuta*, *i. chronica*. Acute impetigo is not usually preceded by any great constitutional derangement. An inflamed patch pretty well defined precedes the eruption of the pustules. Acute impetigo is always also *i. figurata*, though *i. figurata* is sometimes a chronic affection. The duration of acute impetigo is from two to three weeks. Chronic impetigo sometimes lasts for years. The two most obstinate forms are impetigo *sparsa* of the beard, whiskers, moustache, and inside of the nares; and impetigo *scabida* of the lower extremities. In the former case the duration is due to the repeated eruption of fresh pustules; in the latter to the continuance of the formation of pus under the old thick crust. No disfigurement to the face results from the most severe impetigo. The crust after a long or shorter time separates, leaving merely a reddish stain, which quickly disappears.

Willan figures six varieties of his genus *porrigo*: of these—

P. larvalis and *p. favosa* are merely varieties of impetigo.

P. furfurans is a species of *eczema*.

P. scutulata is *tinea tonsurans*.

P. lupinosa is *tinea favosa*, and

P. deculvans is *alopecia circumscripta*.

Bateman's description of *p. scutulata* is most confused; it certainly does not apply to Willan's figure. The latter is a faithful portrait of a common disease; the former applies to no known disease of the scalp, but to separate stages of many diseases having no relation chronologically or pathologically to each other. No age is exempt from impetigo; but *i. faciei* and *i. capitis* are more common in children than in adults; while impetigo of the extremities is far more frequent in adults.

The inflamed lymphatic glands occasionally suppurate in children of a strumous diathesis, and when the seat of tubercle.

The characters by which *tinea sycosis* or *mentagra* is distinguished from impetigo are well given by ‘Azenave.

‘When impetigo,’ he says, ‘is limited to the upper lip or chin, it may be mistaken for *sycosis*; but in the former the pustules are small, arranged in groups; they suppurate completely, and give rise to thick crusts: while in *sycosis* the pustules are distinct; they suppurate to a small part of their extent only—a sixth or eighth, for example; they give rise to a dry, hard, black scab, which is subsequently, as it were, suspended on the middle of the hair; and finally they are succeeded by tubercular indurations, which constitute a secondary phenomenon of the greatest importance.’

The pustules of *ecthyma* are larger and seated on a base. The crusts of *tinea favosa* are dry, of peculiar shape, and a microscopic examination shows their vegetable nature. The vesicles of *eczema* have no connection with the hair-follicles, though the

¹ *Practical Synopsis of Cutaneous Diseases*, p. 168.

inflammation may involve the hair-follicles of the part, and so eczema and impetigo be combined as in one variety of eczema impetiginodes. The crusts of eczema are thin and pale, and when they crack, oozing of a thin alkaline fluid takes place. The pus of impetigo is slightly acid.

Impetigo appears to be contagious. It is very common to see several children in the same family suffering at the same time. It does not spread, however, as tinea tonsurans so often does, through a large assembly of children, *e.g.* a school. Impetigo evidently spreads by contact, and the pus cannot be wafted, as the spores of the trichophyton can, from one to another. The usual medium of conveyance of the pus of impetigo from one child to another is some article of wearing apparel, *e.g.* a cap or bonnet. Children suffering from impetigo of the head or face often have impetiginous pustules on their fingers from picking the parts primarily affected. Cazenave denies any form of impetigo to be contagious. Willan and Bateman thought that form alone contagious which is characterised by the eruption of *achores*. Dirt is a very common exciting cause of impetigo, so also are sugar and stone-dust; the foreign particles collect in the orifices of the hair-follicles, and suppurative inflammation of the follicles is the result. Impetigo of the occiput, Mr. B. Squire says, is always due to pediculi. Impetigo shows no special tendency to affect the weakly or strumous, and is certainly rare in the rickety. It is an infrequent syphilide.

Treatment. In the acute form, a mild aperient, salines, and a simple unstimulating diet, with tepid water as a local application, are generally all the remedies required. When the disease has lasted some time, all crusts must be removed, either by the steam of hot water, or by bread-and-water poultices. It is frequently necessary to remove the hair in order to get the crusts away. The head cannot be shaved; but with a pair of fine scissors the hair can be cut close to the scalp. Patience is needed for this purpose, if the greater part of the scalp be affected. After the removal of the crusts, spermaceti ointment or washed lard, or sweet oil and soap and water, night and morning, often suffice to effect a cure of masses of most repulsive-looking disease. Should these means fail and new pustules continue to appear, a brisk mercurial aperient, *e.g.* calomel and jalap, or calomel and colocynth pill, followed by a grain of quinine three times a day, with ten or fifteen minims of dilute sulphuric acid, will quickly bring the great majority of cases to a successful end. Quinine often seems to act almost as a specific. After the separation of the crusts, a stimulating ointment is sometimes required to prevent the continuance of suppuration. Unguentum zinci: ung. hyd. nitatis; ung. hyd. nit. oxid.; ung. sulph. ioidid.: and ung. sulphuris hypochloritis, are all occasionally useful, and one will sometimes answer when the others have failed, and without the reason being apparent.

Several doses of alterative aperient may be required in the course of the treatment. In obstinate cases the waters of Harrogate and those of Aix-la-Chapelle have been found of much service. In impetigo of the parts on which the whiskers, beard, and moustache are seated, and of the inside of the naves, epilation is often essential for a cure. The moment the slightest swelling or redness is seen at the point where a hair emerges from the skin it should be removed. The inner root-sheath comes away with the hair; and if examined microscopically, the epithelium thus detached is found to be swollen; and often when no trace of suppuration is visible externally, pus-globules are found between the hair and the inner root sheath. When the hair is pulled out, the pustule aborts, as it is termed. The iodide of sulphur ointment, and bitter-almond emulsion one ounce, are the best local applications. Care must be taken to prevent children tearing off the scabs with their nails. The parts itch and feel stiff; and consequently it is with difficulty children are kept from affording themselves temporary relief by picking and scratching the part.

Ecthyma.—The pustules by which ecthyma is distinguished are the phlyzacious. They are large: rarely, however, exceeding a pea in size; with red, moderately-elevated, and hardish bases. Each pustule is followed by a brown scab, which is very adherent to, and somewhat sunken or imbedded in, the hard base. The scab forms two or three days after the eruption of the pustule. When the crust separates, a deep red stain, a small ulcer, or a cicatrix remains.

Ecthyma runs an acute or a chronic course; the former is, however, comparatively rare.

The acute form is preceded by slight constitutional disturbance, loss of appetite, and deranged alvine secretions; rarely by febrile symptoms. The pustules are generally limited to a small part of the surface; the shoulders and neck are their most common seat. A sharp, burning, pricking pain often precedes the eruption of the pustules. In very rare cases several of the pustules coalesce. The lymphatic glands to which the lymphatics of the part lead are usually enlarged.

The duration of acute ecthyma is one to two weeks. This is the *ecthyma vulgare* of Willan.

The pustules of chronic ecthyma are scattered at some distance from each other. They are most frequently seated on the extremities, now and then on the extremities and trunk; and in infants they are seen also on the hairy scalp. The long duration of the disease (several months) is due to the eruption of crop after crop of pustules. When the disease affects persons of broken-down health, the pustules are often filled with a reddish sero-purulent fluid; the *areola*, instead of being red, is dusky or purple; and ulceration of an unhealthy character follows the separation of the scab: this is *e. cachecticum*.

No variety of ecthyma is contagious.

Chronic ecthyma indicates a low state of the constitutional powers; and *e. cachecticum* occurs only in the aged and those exhausted by bad diet, over-exertion, mental distress, and other depressing causes. *E. cachecticum* is sometimes accompanied by purpura hemorrhagica, and then the *areola* is purple. This variety has been called *e. luridum*.

Ecthyma chronicum occasionally follows the acute specific diseases. Pregnancy is said to be a predisposing cause of the disease. It is one of the most common of the syphilides.

Ecthymatous pustules are produced by the application of various irritants to the surface. The grocer's itch, as it is called, is produced by the irritation of sugar. Stone-masons now and then suffer from the same disease. The well-known pustules that follow theunction of tartar-emetic ointment are examples of ecthyma; only the pustules resulting from the application of this agent are umbilicated.

Scabies is often complicated, especially in young children, by large ecthymatous pustules; as are also, though much less frequently, prurigo and lichen.

The special structure of the skin which is primarily affected in ecthyma is unknown. Biett says that the inflammation originates in the sebaceous follicles: Hilbert and G. Simon, that when tartar emetic is applied to the skin, the orifices of the hair-follicles are first affected; and they attribute the umbilication to the tying-down of the centre of the pustule by the hair-follicle.

Treatment.—In the acute form of ecthyma little is required to be done. One or two doses of alterative aperient, followed by simple salines; a simple but not too low diet; and tepid water frequently applied to the inflamed part, are all that are necessary and useful.

In the chronic forms the health is generally and sometimes very much deranged; the patient weak and exhausted. Generous diet, moderate quantities of wine, quinine, or bark, and the mineral acids, serpentaria, and cod-liver oil, and steel, are one or all necessary to effect a cure. Daily tepid baths are useful. Taraxacum and sarsaparilla, with nitro-muriatic acid, seem occasionally to be of much benefit. Opiates are sometimes required at night.

Order 6.—PAPULÆ.

Strophulus, or red gum, as it is vulgarly called, is a common papular disease proper to children from birth to the end of the first dentition. It is characterised by the eruption of small papulæ, red or paler than the healthy skin, scattered or grouped, and attended by trifling itching.

Many writers on diseases of the skin consider strophulus and lichen to be the same disease.

Several varieties have been described and most admirably figured by Willan. When the papules are scattered over the skin, with small red spots interspersed among them, the disease is called *s. intertinctus*. When the papules are crowded into groups, and the skin between is more or less red, it is *s. confertus*. 'Sometimes,' Bateman says, 'though rarely, a variety of the *s. confertus* appears on the legs, spreading upwards even to the loins and navel, producing a general redness of the cuticle (not unlike intertrigo), which cracks and separates in large pieces, occasioning much distress to the child. It is liable to recur at short intervals for the space of two or three months.' It is in children of seven or eight months old that this severer form of *s. confertus* occurs. When, for three or four weeks, circular patches of papules appear in succession, each patch lasting four or five days, the disease is *s. volaticus*.

Strophulus candidus is the name applied to an eruption of white, rather large, papules, which appear occasionally on the loins, shoulders, and upper arms of children of about a year old. There is a danger of mistaking the hard pale elevations produced in some children by the bite of a flea for this disease; a vesicle sometimes results from the bite of the same animal.

Strophulus albidus is a rare disease. It is doubtful if Bateman (judging from his description) ever saw a case. Willan's figure is perfect. The so-called papules are really sebaceous follicles, distended by their secretion. The small elevated opaque dead-white spots scattered in numbers over the face are so striking in appearance as at once to rivet the attention.¹ Willan's *strophulus albidus* is, then, a form of *acne*. Hebra it was who pointed out the real nature of this affection.

Strophulus is a disease of no practical importance. It is not contagious. It generally depends on some disorder of the stomach and bowels of the child; this being itself often secondary to dental irritation, or to improper diet.

Treatment.—A knowledge of the causes of *strophulus* points to the treatment. A gentle antacid aperient, as rhubarb and magnesia with an aromatic; or an antacid without any aperient, as the *mistura cretæ*, should be given; attention should be paid to the diet, which is so often faulty in the child, and the use of the gum-lancet may be required. The eruption is of use, by pointing the attention to some error which, if allowed to go on uncorrected, might lead to more serious trouble. It is only in the gravest form of *s. confertus* that occasional bathing with faintly alkaline gelatine water is required.

Lichen.—The papulæ of lichen are very small solid elevations of the cutis, perceptible to the touch, redder than the adjacent skin, which cannot be even temporarily removed by pressure, though they may be made for the instant paler. The papules itch and tingle. As the redness fades, and the papules disappear, trifling desquamation of the cuticle over them takes place. Lichen commonly affects a limited part of the surface only, e.g. the hands, forearms, trunk, face. The back of the hands and the outer aspect of the forearms are common seats. The papulæ are generally arranged in groups.

Lichen occurs in an acute and in a chronic form. Lichen simplex is accompanied, and sometimes preceded, by trifling febrile disturbance. The papules are bright in colour, and appear first on the face and arms, then extend to the trunk and lower extremities; it is an acute affection, lasting from ten to twenty days. It has been mistaken for measles and for scarlet-fever. L. simplex occasionally returns at long intervals in the same individual.

Lichen *circumscriptus*, *l. urticatus*, and *l. lividus*, may be regarded as chronic varieties of lichen simplex.

In lichen *circumscriptus* the papulæ are arranged in irregularly circular groups. As those first evolved fade, others appear at the margin of the patch; in this way the disease may be prolonged for many weeks. Lichen *gyratus*, in which the papules

¹ In University College Museum there is an excellent wax model, by Mr. Tuson, of the face of a child suffering from this disease. It was made from a patient of the writer's.

are arranged so as to form a twisted band, is probably a form of lichen circumscriptus of syphilitic origin.

Lichen lividus is seen in old persons, and chiefly on the lower extremities. The papules are dusky red, or livid, and frequently purpuric spots are interspersed among the papules. Hebra considers it to be a species of purpura, and calls it purpura papulosa.

In lichen urticatus, the more permanent papules are preceded by small wheals; the papules becoming apparent as the wheals subside. The papules are throughout the whole course of the attack larger than in any other variety of lichen. Hebra and G. Simon consider it to be a variety of urticaria, and call it urticaria papulosa.

Lichen pilaris is distinguished by the passage of a hair through the centre of each papule. It is probable that it would, as G. Simon has stated, be more correctly described as a variety of acne.

Lichen agrius is a much more serious variety. A considerable amount of local inflammation attends the eruption of the papules, which are usually limited to circumscribed patches of some extent. The heat, tingling, and itching are very troublesome, and the scratching to relieve the last-mentioned symptom increases the local inflammation. Warmth and internal stimulants, alcoholic or other, increase the itching. Lichen agrius may disappear in a fortnight or three weeks; usually, however, it runs a chronic course, crop after crop of papules appearing on the inflamed patch. Ultimately the skin of the part becomes thickened and cracked; a serous oozing may take place from the surface abraded by the nails, and suppurative inflammation may be set up, and then crusts of various degrees of thickness are formed on the surface. Lichen agrius in this state may be mistaken for psoriasis, for eczema, or for eczema impetiginodes; and it is only by the history, and by a careful examination of the margin of the patch, that the primary nature of the affection can be determined.

The prickly heat of hot countries is merely an aggravated form of lichen simplex. It is called lichen tropicus.

Hebra has described a very rare form of lichen, to which he has given the name *l. ruber*. It has also been termed *l. planus*. At first there is an eruption of milium papules; the eruption is accompanied by very little itching. The papules increase in number till they occupy entire regions, or even the whole surface of the body. The appearance of the disease is then quite peculiar. The integument is universally reddened, covered with numerous thin scales, and so infiltrated that when a fold of the skin is taken up it is found to have more than twice the normal thickness. The flexion of the joints may be impeded by the thickened skin. As the disease spreads over the whole surface, the patient falls into a state of marasmus, and the case generally ends fatally.¹

Lichen is not contagious. Persons of a nervous, excitable temperament are specially liable to it. Women more frequently suffer than men. It is more common in spring and summer than in autumn or winter. Some derangement of the stomach or intestines is usually connected directly with the attack.

The investigations of Gustav Simon seem to prove that the papules of lichen, strophulus, and prurigo are not, as some have asserted, the papillæ of the skin inflamed or enlarged. They have no connection with the papillæ; but are produced, according to the same observer, by the effusion of serosity into the substance of the skin. Lichen, strophulus, and prurigo are considered by Cazenave to be primarily lesions of sensibility—true nervous affections; the degree of itching bearing, he says truly, in many cases no relation to the number of the papules.

Treatment.—A mercurial at bedtime, followed by a saline aperient in the morning, once or twice a week, a carefully regulated, simple, unstimulating diet, the avoidance of heating exercises and clothing, a well-ventilated room, and a gelatinous or mucilaginous bath every night to allay irritation, will bring the majority of cases of lichen to a favourable termination. When the inflammatory symptoms have been

¹ *Sydenham Society's* edition of Hebra, vol. ii.

reduced, and the disease has assumed a chronic form, arsenic will effect a cure. Fowler's solution (liquor arsenicalis) in five-minim doses may be given three times a day. Sulphur-baths have proved useful in some cases. It is rarely that local stimulating applications are of service. Ointment containing calomel and camphor, and iodide of mercury, are recommended by Rayer; but certainly prove injurious in the great majority of cases which seem best suited for their employment.

Bark with dilute sulphuric acid, and a generous diet with wine, are the proper remedies in lichen lividus.

The most obstinate forms of lichen are *l. pilaris* and *l. urticatus*. In the treatment of the former the inunction of lard every night, followed by an alkaline bath, soap and water, and friction, are most useful. Sponging the parts with vinegar and water, or lemon-juice, will sometimes allay the intolerable itching in *l. urticatus*. The subjoined lotion is recommended by Dr. Thompson for the same purpose:—

℞ Acid. hydrocyan. dil. ʒjss.; potassæ liquor. ʒj.; aq. rosæ ʒ vss. M. This lotion to be applied to the part when the itching or pain are troublesome. For *l. ruber* the remedy is arsenic in full doses.

Prurigo is characterised by a scattered eruption of very slightly raised, flat, and rather broad papulæ, differing little, if at all, from the colour of the skin. These papules are the seat of troublesome itching. It is sometimes very difficult to detect the papules, in consequence of their colour, their flatness, and their breadth. Sometimes they appear, as it were, buried under the cuticle, and the papules which can be discovered by the most careful examination are often very few compared with the severity of the itching. Stimulating drinks, spices, heating exercise, trifling contact of the clothes, and change of temperature increase this most troublesome symptom. Sometimes the patient, comparatively free during the day, no sooner is warm in bed than the itching becomes so intolerable as altogether to prevent sleep. The excessive itching of the papules never fails to lead to their apices being torn by the nails. Blood and serosity ooze from the abraded surface, and a little black crust occupies the summits of many of the papulæ. The lines of abraded cutis, so common in scabies, are comparatively rare in *prurigo*. In the latter it is the papule itself which is torn. When the itching is accompanied, as it sometimes is, by a sensation as of insects crawling over the part, the disease is called *prurigo formicans*. This is a most obstinate and severe variety. Wheals of urticaria occasionally appear when the part is rubbed or scratched violently. *Prurigo* is common in the aged; the itching being most constant and severe, the patient having little rest day or night. When *prurigo* occurs in old people, it is called *p. senilis*. By the irritation and want of sleep it occasions, *p. senilis* has sometimes shortened life. It is in old persons especially that the papulæ most easily escape detection. *P. formicans* and *p. senilis* are usually very obstinate, lasting months and even years. When the itching is moderate in severity, as is not unfrequently the case in young persons, the disease is *p. mitis*. This variety disappears in from a few hours to a few days.

There is no line of demarcation to be drawn between these three varieties of *prurigo*. The greater or less degree of itching and the age of the patient are very insufficient grounds for the foundation of species. Hence it has been proposed to divide *prurigo* into general and local *prurigo*.

The shoulders, neck, and outer aspect of the arms, are the most common seats of *prurigo*.

Old persons who suffer from *prurigo* are also frequently the subjects of lice; and it has been supposed that the condition of skin on which the *prurigo* depends is favourable to the propagation of the lice. G. Simon, on the contrary, thinks that it is in many cases the rubbing and scratching of the skin consequent on the presence of the lice which induces the papular eruption. No doubt the want of cleanliness, so common in old age, is a cause for the presence of the parasite and of the eruption.

The papules of *prurigo* bear a close resemblance to those of scabies; and cases of scabies, in which vesicles are few and not very perfect, have repeatedly been mistaken

for prurigo. Bateman says *p. mitis* often terminates in scabies: he might more correctly have said scabies is often mistaken for prurigo. 'As to the changes of the skin in prurigo, I,' writes G. Simon, 'endeavoured to satisfy myself by the examination of papules, which I cut, with a small piece of the adjacent skin, from living people; and I found exactly the same state as in lichen. The epidermis was not detached, the papillæ of the skin were not enlarged, and the fibres of the cutis were unchanged.' He concludes that the papule in prurigo, as well as in lichen, is produced by the presence of serosity in the substance of the skin at this spot. If a papule of prurigo be punctured with a fine needle and then compressed, a clear fluid oozes from the wound; if a papule of lichen be punctured with equal care, blood escapes. Simon attributes the difference to the greater vascularity of the papules in lichen, and the consequent impossibility of not puncturing a vessel. The little serosity that would otherwise be visible is concealed by the blood. Hebra says each papule is formed by a collection of fluid in the deeper layers of the epidermis.

Prurigo, like lichen, is considered by Cazenave to be a disease of sensibility. Of the origin of the nervous affection, nothing is known. The retention of some of the urinary constituents in the blood has been stated, but hitherto without proof, to be a cause of prurigo. The itching of the skin in jaundice is familiar to all; and in some cases in which that symptom has been most marked, a papular eruption has been present. Whether in these cases the papular eruption is the consequence of the scratching, it is impossible to say. The subjects of prurigo often suffer from hæmorrhoids.

Treatment.—If the patient be young and strong, the diet should be simple and unstimulating, and the bowels kept freely open by such a mixture as the following, taken two or three times a day: \mathcal{R} . Magnes. sulph. ʒjss.; acid. sulph. dil. mxxv.; inf. gentian. co. ʒjss. Misce. A dose of calomel and colocynth, or blue-pill and colocynth, should also be given at bedtime once or twice a week. Tepid alkaline baths should be used every other night. Sulphur vapour-baths are useful when aperients are no longer indicated by the pulse and general state of the patient. Sea-bathing has sometimes effected a cure.

In the aged, and in young persons of broken health, good diet and even wine are required. Tonics, especially quinine or bark with mineral acids, are useful. Frequent washing with soap and water, and daily change of body linen, are essentials. Tepid alkaline baths and sulphur vapour-baths are also of much service. Diuretics and cholagogues have been given when the disease has been supposed to depend on the retention in the blood of the urinary or hepatic secretions.

Cazenave says, that since lichen and prurigo are really true neuralgic affections, they should be treated as such. And he adds that the practical results he has obtained afford fresh proof of the correctness of his views as to the nature of these most troublesome affections. 'In the majority of cases the employment of antispasmodics or of antiperiodics suffices,' he says, 'to modify completely the hyperæsthesia. I have had recourse,' he adds, 'with happy results to ammoniacal sulphate of copper, to datura-stramonium, to extract of aconite.' The last he gives thus: \mathcal{R} . Extract. aconit. gr. xv.; conf. rose q. s. ut ft. pil. xx. One pill night and morning. Sulphate of quinine he gives in doses of from 3 to 5 grains per diem, and continues it for one or two weeks. Of liquor arsenicalis, in common with all writers on this subject, he speaks in the highest terms; but he considers that it acts not only by modifying the action of the skin, but also as an antiperiodic.

Local prurigo.—There are many species of local prurigo, but they differ only in their seat: thus there are *p. podicis*, *scroti*, *pudendi*, *preputii*, *urethralis*, &c., according to the part affected.

Local intolerable itching is always called prurigo, but it is by no means always the consequence of a papular eruption. Itching of the anus and of the labia pudendi is a common consequence of congestion of the large veins of the parts, of hæmorrhoids, of ascariæ in the rectum, of an overloaded lower bowel, of the early stage of cancer of the uterus and lower bowel. Local eczema is a common cause of intense itching.

Treatment.—Cleanliness and the avoidance of scratching are the first essentials

to a cure. If the anus be the seat of the trouble, it should be washed after stool and then carefully dried. The liver and bowels should be freely unloaded, in order that all congestion of the parts due to impediment to the onward flow of the blood in the portal vein may be removed. Leeches to the anus are often useful when it or the parts in its vicinity are the seat of the prurigo. Tepid water, or lotions containing an alkali, opium, prussic acid, acetate of lead, calomel and lime-water, acetate of ammonia, vinegar, have all been used with advantage, and have all failed in other cases to afford relief. The bichloride of mercury and lime-water, two grains to the ounce of lime-water, is one of the most efficacious local applications. Ointments containing lead, nitrate of mercury, or ammonio-chloride of mercury, sometimes check the itching when the lotions recommended have proved useless. The patient should always keep the preparation which answers best by his bedside, so that when the heat of the bed renders the itching severe, he may bathe or anoint, instead of scratching, the part. When eczema is the cause of the itching, a solution of nitrate of silver and the ung. sulphuris-hypochlor. are the most frequently successful applications.

Order 7.—SQUAMÆ.

Pityriasis.—Trifling redness of a limited portion of the skin, with furfuraceous desquamation of the cuticle covering the part, are the characters by which pityriasis is known. *Pityriasis capitis* is the most common variety. This is the disease known to nurses by the names scurf and dandriff. The head itches, and directly it is rubbed, quantities of little scales, formed of epithelium, are detached. A similar affection occasionally occurs at the bends of the joints and over a limited extent of the trunk. When it has existed for some time in a severe form on the head, the hair, often comes out in considerable quantity. It grows thin, but does not come off in patches, or to such an extent as to cause baldness.

Pityriasis rubra is the name formerly, and often still, applied to the disease when the redness is more decided, and there is roughness, rather than detached scales, on the surface. It occurs in patches. The most common exciting causes of *p. rubra* are exposure to the rays of the sun or to a cold dry wind; and frequent wetting of a part of the skin and then drying of it by evaporation. Children often produce *pityriasis rubra* of the lips by wetting the surface of the skin around the mouth with the tongue. No doubt many of the cases called *pityriasis rubra* are really examples of the driest forms of eczema.

The term *Pityriasis rubra* has also been applied by Hebra to a specific disease of the skin, quite distinct from all the recognised varieties of pityriasis, but presenting a close anatomical affinity to psoriasis, or to eczema in its chronic desquamating stage. This use of the term has of late been generally adopted.

Hebra's *p. rubra* is a rare disease of very chronic progress. It occurs for the most part in persons who are otherwise in the enjoyment of good health, and appears to be incurable. It commences with congestion of the skin, which is either universal from the beginning or soon becomes universal, and is speedily attended with a tendency to the abundant formation and separation of the epidermis in large dry flakes. There is little or no infiltration or thickening of the congested skin at any time, and little or no itching or other sensory discomfort. The congestion and desquamation, however, persist, and the scales often accumulate or are shed in considerable quantities. The nails are apt to suffer as they do in eczema and psoriasis. For the most part the health does not suffer. But it is said that after the disease has persisted for many years the skin is apt to become tender and more or less disorganised, and the patient is apt to fall into ill health attended with loss of appetite, emaciation, and debility.

The disease chiefly resembles chronic eczema and psoriasis. But there seem to be obvious differences. Its onset and early phenomena appear to be characteristic. There are no vesicles and papules, and no fluid exudation as in eczema. It does not occur in patches, as eczema and psoriasis usually do. And there is (at any rate until quite the latest stage) an absence of the thickening and cracking of the skin which are observed in the chronic and diffuse forms of eczema and psoriasis.

Treatment.—A solution of borax as a detergent, mild astringent ointments, and the avoidance of hard friction, as by the use of a hard hair-brush, are usually all that are needed in the treatment of pityriasis capitis. If these means fail, or if the disease be very troublesome, the following liniment will be found a valuable aid: \mathcal{R} hydrarg. ammon. chlorid. \mathfrak{zj} .; ol. olivæ \mathfrak{zj} . M. To be applied to the head with a camel-hair pencil. When the hair falls out, a local stimulant often stays the mischief. Equal parts of acetum cantharidis and spirits of rosemary form a good liniment.

In simple pityriasis rubra, zinc ointment and the avoidance of exposure to the exciting cause generally effect a cure.

Aperients are frequently required. In severe, extensive, and obstinate cases, vapour and sulphur baths are often useful.

For Hebra's pityriasis rubra, warm baths and oleaginous and other emollient applications are serviceable.

Psoriasis.—The disease now commonly known by the name of psoriasis was formerly, and is still by some, divided into two genera, viz. psoriasis and lepra. This distinction is based on no real difference between the two affections.

Psoriasis is a chronic disease characterised by slightly-raised red patches covered by white shining opaque scales.

The varieties of psoriasis are founded on the shape, size, number, or situation of the patches. Thus, when the spots are circular, small, numerous, and irregularly scattered over the skin, the disease is *p. guttata*, when they are long and broad, it is *p. diffusa*; when they are ring shaped, the centre assuming a healthy appearance while the disease is spreading at the circumference, it is *p. vulgaris* or *p. circinata*. It was to patches of psoriasis of this shape that the name *lepra vulgi* was applied. When the patches are in the form of twisted bands, a very rare variety, it is called *p. gyrata*.

As to the varieties named merely from the part affected, there are *p. præputialis*, *scrotalis*, *labialis*, *palpebrarum*, *palmaris*, *dorsalis*, &c.

Psoriasis in all its forms runs a very chronic course, lasting not infrequently for many years. When cured, it is prone to recur. Some persons have an attack of psoriasis every year, some two in a year. Spring and autumn are said to be the seasons when these attacks occur.

The spots of *p. guttata* are from a quarter to half an inch in diameter, their centres are raised, and as they fade their centres heal first. *P. guttata* occurs on the trunk and extremities. The spots are often irregularly scattered over the whole surface. It is common for a few spots to be present in other varieties of psoriasis. The twisted bands of *p. gyrata* are said to be formed by the close approximation of separate spots of *p. guttata*.

P. diffusa begins in rather broad irregularly-shaped angular patches, which subsequently coalesce. Its most common seat is the extremities. The front of the leg, from the patella to the ankle, is occasionally covered with an unbroken patch of *p. diffusa*. The outer aspect of the forearm, from the elbow to the wrist, is also now and then the seat of a similar large patch. When *p. diffusa* is very severe and long continued, it has been called *p. inveterata*.

When the ring shaped patches of *p. vulgaris* attain a very large size, the scales are sometimes wanting over a considerable extent of the ring. Under such circumstances there is a large red elevated ring, with patches of scales here and there. Within this ring are occasionally rings of *p. vulgaris* entirely covered with scales. The local accumulation of scales in psoriasis of the scalp is often enormous. When psoriasis affects the backs of the joints of the fingers, most painful cracks form; the scales in this situation are few. The itching is very troublesome in some forms of psoriasis, attaining its maximum when the disease affects the scrotum or the labia pudendi.

Dr. McCall Anderson, in his work on psoriasis and lepra, has described a form of psoriasis in which the scales are very thick, and so much thicker in the centre of the

patch than at the circumference as to give to the patches on a superficial examination the appearance of crusts of rupia.

The red patches of psoriasis are due to inflammation of the cutis ; the scales to excessive formation of epithelium on the inflamed surface.

Neuman ('Wochenblatt der Gesellschaft,' 1867), from his minute researches into the local structural changes in psoriasis, concludes that psoriasis is an affection of the skin involving chiefly the papillæ and the superficial layer of the corium, of which the characteristic feature is the excessive formation of epidermis.

Inflammation of the skin, attended by the effusion of the ordinary products of inflammation, leaves behind, supposing the patient to be disposed to the disease, a state of the part favourable to the formation of a patch of psoriasis.

Thus a lad was in University College Hospital suffering from psoriasis. The disease had almost disappeared, when herpes zoster occurred, ran its ordinary course, and healed ; but no sooner had the scabs separated, and that stage been reached in which only a faint red stain indicates the seat of the herpetic patches, than each reddish spot covered itself with scales in fact was converted into a patch of psoriasis. A blister was subsequently applied to the lad's thorax. When it had healed, and the stage of simple redness was reached, the part on which it had been placed covered itself with scales. It may be, of course, that the herpetic inflammation and the inflammation excited by the blister acted especially by stimulating the vessels or the nerves or the formative power of the part. Probably all were affected ; the formative power being disproportionately affected from the general state of the health.

As bearing on this question, it is interesting to note that, in *p. guttata*, if the points at which the spots are originating be carefully sought out and examined, the redness and the scales will be seen to be forming at the orifice of the hair-follicles, not in all instances, but in the majority.

Psoriasis occupies the drier and coarser parts of the skin. Hence it is most common on the knee, just under the patella ; and at the elbow, on the skin covering the olecranon process of the ulna. In regard of situation, it occupies the parts which differ most in texture from those occupied by eczema. When the patches are very numerous or very large, and spread from the back to the front of the arm, or from the front of the knee to the ham, the disease is worse or more extensive in the coarser textured parts. Thus parts at which the sweat-glands are the most abundant are the chosen seats of eczema, while the same parts are rarely the seat of psoriasis.

The loins, according to Mr. B. Squire, are more frequently affected than any other parts of the trunk.

Psoriasis is often connected with deranged stomach, and especially with a very subacute gastritis.

It is never communicated from one person to another. A tendency to psoriasis is undoubtedly hereditary. Psoriasis is a common syphilide. Whenever it affects the soles of the feet or the palms of the hands, the probability of its origin in constitutional syphilis should be investigated.

Care must be taken not to confound eczema of the palms of the hands with psoriasis of the same part. There is occasionally a difficulty in separating the two. In fact, eczema of this part is occasionally figured as psoriasis ; the thickness of the cuticle prevents its being raised into vesicles, the fluid formed is small in quantity and escapes notice ; the consequence is that the chief feature of the case is the peeling of the skin of the palm. The most frequent exciting cause of the eczema, viz. carbonate of soda used by women in washing, &c., so changes the cuticle as to aid in the production of a similarity between the two affections. Excluding, then, the syphilides, psoriasis of the palm of the hand is a much rarer disease than is generally supposed, and non-syphilitic psoriasis of the soles of the feet is very rarely, if ever, seen.

The drier forms of eczema of the neck, extremities, and trunk are occasionally mistaken for psoriasis. The different situation occupied by the two diseases suffices at once to prevent the error, by suggesting a doubt as to the case being what it at first sight resembles. A careful examination of the part shows the apparent scales of eczema to be formed of dried vesicles.

Treatment.—Attention should in all cases of psoriasis be paid to the state of the stomach, in order that anything approaching to subacute gastritis may not escape

observation. Should it be indicated, then the diet must be carefully regulated, and the internal affection made the first object of treatment. In cases where there is no evidence of an inflammatory state of the mucous membrane of the stomach, the treatment is determined by the state of the local disease, and by the general condition of the patient; if the patches be hot and bright red, an antiphlogistic regimen and venesection, or aperients, or both, according to the age, the pulse, and the strength of the patient, are to be first employed. Should there be no unusual heat of the part from the first, or after the active symptoms have been subdued by the remedies above mentioned, liquor potassæ, iodide of potassium, tincture of cantharides, and especially arsenic in the form of Fowler's solution, are the most potent internal specifics. Liquor potassæ and iodide of potassium require to be given in full doses in a large quantity of some bland fluid.

Tincture of cantharides, an old remedy, was employed by Bielt, who thought very highly of it, and by it alone cured a large number of obstinate cases. The dose to commence with is five minims twice a day; it may be gradually increased till thirty or forty minims are taken, in divided doses, during the day. Its action must be carefully watched. Nausea, colic, diarrhoea, and troublesome erections of the penis, are said by Chazeneuve to be the occasional consequences of its employment.

Arsenic, however, is undoubtedly the most potent of the remedies used in the treatment of all varieties of psoriasis. The dose of Fowler's solution is three minims three times a day, gradually increased till eighteen or twenty minims are taken, in divided doses, during the day. Each dose should be taken on a full stomach, *i.e.* directly after meals. Its effects must be attentively watched. When any signs of its disagreeing occur, it should be omitted for a few days, and then resumed in smaller doses. The evidences of too strong action are inflammation of the tarsi, ophthalmia, nausea, colic, diarrhoea, and a troublesome, dry, paroxysmal cough. Other internal remedies which have been said to be occasionally of service are the decoctions of dulcamara and of mezereon, bichloride of mercury, calomel, and pitch. The decoction of dulcamara may be used with advantage as a vehicle for the more potent tincture of cantharides and liquor potassæ arsenitis. Copaiba in small doses, originally recommended by Hardy, is said to have proved efficacious in cases not benefited by arsenic. (Living, 'British Medical Journal,' November, 1869.)

Local remedies suffice in many cases for a cure; though in all local are greatly assisted by internal remedies.

The most potent external application is unguentum picis. The addition of a little creosote increases its efficacy. Nitrate of mercury ointment may be used when the patches are of small extent. Tepid vapour, and sulphur baths are all occasionally of service.

Ichthyosis is properly classed with the squamous order. The name, derived from a fancied resemblance which its scales bear to those of a fish, refers rather to their abundance than to their arrangement, as the absence of imbrication marks the complaint in every stage and variety. In many cases the scales are very thick, disposed as so many small squares, and often rendered dark or nearly black from continued exposure; they are specially developed in the vicinity of the joints, as the knees, ankles, and hips; occasionally on the clavicle, and in females around the nipple.

A good illustration of ichthyosis is afforded in the following instance of S. B., a girl 14 years of age, admitted into hospital in 1864. The scales covered every part of the body, except the soles of the feet and the palms of the hands, where the skin was only rough; they were also absent on the ball of the thumb and the upper lip. Their greatest development was attained on the hips and elbows, but the neck, back, and outer surface of the limbs were severely affected. The large scales were irregularly fissured, and some of them curled at their margins. Thickest on the knees, they existed as large flakes on the abdomen and the thighs. The forearms on either aspect were covered with dark rectangular scales, which became circular or oval towards the wrist, and slightly depressed in their centre.

Ichthyosis is always congenital, and should be considered rather as a malformation than as a disease. It is never contagious.

Such are the characters of ichthyosis as they occur in extreme examples. There are, however, many cases no less typical, but which differ from the preceding chiefly in the disposition of the scales. The latter are notable for their size and tenuity, as well as for the rapidity with which they are shed and again renewed. The skin also inclines to a reddish hue.

In a *third* kind, an intermediate stage is represented between what might be termed pityriasis and ordinary ichthyosis. It is a far more frequent species than those just described, and its scales are thinner and more abundantly diffused than in the latter affection. In common with the rest, this complaint is congenital, and as such it differs from hereditary psoriasis in not being declared, or at any rate most rarely so, at the time of puberty, or yet at a later age. The most usual period for its primary manifestation is from the third to the sixth month, and seldom is it delayed beyond the first year. It commences generally on the scalp and face, sometimes on the back, extending from thence over the whole surface, and varies from one to two or more years before its entire effect is accomplished. In some of the worst instances of its occurrence, it is associated from birth with a deficiency of the eyebrows and eyelashes; and in cases less pronounced these may be but partially present. Although at its origin the face is usually involved, the disease in its progress sometimes appears partially to forsake this part, and to become finally more confirmed on the loins and legs. The patient's garments or bed-clothes, as in psoriasis inveterata, will be constantly covered with numerous scales, which are regenerated almost as soon as shed. The skin everywhere feels preternaturally rough and dry, not excepting the hands and feet; and one distinguishing element of the complaint to be often noted consists in that absence of perspiration, which, in cases of severity, would seem to be complete, the skin retaining its dry character even in the hottest day. As might be anticipated, the condition of the patient thus situated depends in no slight measure upon the seasons, the disease being found to yield to the influence of mild weather, while, on the other hand, it is readily affected or increased by cold. In winter, or in a piercing wind, the patient is pretty sure to suffer, particularly on any surface uncovered, as the face or fingers, or should he afterwards approach the fire or become otherwise heated, the same parts tingle and smart. A similar result will sometimes follow exposure to the sun's rays in summer, which, without flaying the skin, produce great irritation in such a locality as the face. In other cases the feet, around the heels, are apt to become fissured and painful after walking, or much inconvenience is occasioned from the friction of the scales in front of the ankle or at the groin.

A yet lower type of ichthyosis—the lowest of all—I would beg to subjoin. The subjects of it are distinguished by a similar want of perspiratory action of the skin as in the last named, or by its limitation to some particular region. This may be, and most generally is, the palmar or plantar surface, or the axillæ, or the face and neck; and I have known a small space on the loins, or the front of the chest, the only part capable of secreting. Sometimes the spot thus selected constantly perspires, or it is only the great heat of summer which induces it to do so. Again, the presence of scales, although so prominent a feature in all other forms of ichthyosis, is not remarked here; and scarcely can the hand, much less the eye, detect any appreciable difference in the integument from that of the normal state. Such patients are often remarkable for a redness or freshness, as it might be said, of the cheeks, and particularly is this noticeable after the least excitement or exertion. That these cases do in reality pertain to the class under our present consideration is sufficiently attested by the hereditary nature of the complaint, and by the evolution of its higher grades in other members of the same family; and not seldom its occurrence in direct descent. One complication I must likewise add, which, almost always overlooked, deserves mention in this place—I mean its occasional association with prurigo. The latter is in many instances severe, and productive of the utmost annoyance to the patient, whom it may affect at any age, from early life to youth, and beyond it. Towards night especially, exacerbations are wont to occur, as on approaching the fire, or the same takes place from exposure to cold. That this kind of prurigo is dependent upon

the state of the skin itself, and not due to any parasitical influence, is, I think, proved to demonstration by the absence of any such exciting cause, and by the remedies successfully employed for its removal.

The total arrest of all sensible perspiration in ichthyosis, and its partial secretion only in some of the modified forms of this complaint, offer an interesting subject for investigation with respect to the state of the urine. The result of certain experiments which I undertook some few years since on this question¹ pointed to the following conclusions. A considerable increase in bulk was observed in the urine, which was only faintly acid, and of low specific gravity; the rate per cent. of urea was small, although its absolute amount remained nearly the same—a fact which militates against the usually received theory of the elimination by the skin of urea; lastly, the phosphoric and sulphuric acids were hardly, if at all, affected.

Most writers have dwelt on the greater frequency of ichthyosis in the male as compared with the female. My own observations, derived from no inconsiderable number of cases, rather incline the other way, and certainly do not support the opinion that ichthyosis is a special complaint of either sex. Instances have come under my notice of ichthyosis invading the male children only in one family, and in another the female; of its affecting both sexes, the offspring of the same parents; and again of its appearing in a single member alone. The hereditary nature of ichthyosis in some examples is unquestionable, and I have recorded one, in which there was evident proof of the direct transmission of this affection through six successive generations. Instead of proceeding in an immediate line, it will sometimes show itself in a collateral branch of the family; and cases are not rare in which, as far as can be ascertained, no claims of lineage are allowed.

Ichthyosis may exist in the fœtus, and in a most aggravated form. In these cases, the skin appears tightly stretched throughout, and over the trunk and limbs it is ruptured in transverse or parallel lines. The eyes are fixed in consequence of the rigid state of the lids, so likewise are the lips, which are converted into hardened bands, and expose the gums, and no vestige of an external ear is seen. The entire body presents an assemblage of lozenge-shaped spaces or intervals, caused by a separation of the fibres of the cutis, sufficiently numerous and distinct to warrant the appellation of a 'harlequin' fœtus, which is allotted to it. The only museum, as far as I am aware, in the possession of this remarkable class is that of Guy's Hospital, which contains four excellent specimens of this singular deformity of the skin. Although it is to be regretted that no history is attached to them, I was fortunate in learning from Mr. Scarr, of Bishop's Stortford, who presented one of the above preparations to the Hospital, that not only was the mother's labour in this instance perfectly natural, but the fœtus lived for some seconds after its birth: it was the only one of several children that exhibited any indication of ichthyosis, and no hereditary trace could be obtained. I may add, that by the parent the complaint was attributed to a sudden and severe fright she experienced, when attending a country fair at the time of quickening.

Hitherto I have considered ichthyosis as general, and therefore complete; but it is by no means invariably so. Instances are often met with in which it occurs only in a partial form. These betray a roughness of surface varying in degree and extent in different cases, but chiefly observed on the outer aspect of the limbs and on the loins, and most of all in the vicinity of the knees or other large joints. The scalp participates, but irregularly; it may exhibit at a single spot a large, thick, and irregular crust, very adherent, and covered with hair; or in other cases, separate white patches, scarcely raised, but equally tenacious as the last, and penetrated at various points by hair. In the regions which are healthy, perspiration will frequently be found continuous and excessive, as if to compensate for the more general deficiency of the same secretion elsewhere; nor even in winter is it altogether deficient, particularly in such places as the palm and sole. I well remember a young lady, a private patient of Mr. Startin, in whom this disease was entirely confined to the

¹ Naylor, *On Diseases of the Skin*, p. 64.

palmar and plantar surfaces. Her father was similarly but less severely affected, while the rest of the family were quite exempt. Still more recently, an example of this rare affection came under my care at the hospital in a young woman, 20 years of age, who likewise had the complaint limited to the hands.

A case in private is now under my observation of an adult patient, who perspires everywhere except in the face, which is always dry, even in the heat of summer, but without any appearance of scales. Of his two children the younger, a boy aged 3 years, is an instance of general ichthyosis; while the other, also a boy, is entirely free.

From what has now been stated of ichthyosis, it will be seen that I have used the term in a far more comprehensive sense than has hitherto been assigned to it. Considered from this point of view, there are few cutaneous disorders which offer so many and at the same time such distinctive degrees of comparison. It varies from a general roughness of the surface, which may be scarcely perceptible, to a condition of the utmost severity, as in the harlequin fetus; and between these two extremes every connecting link in the chain of development is complete. Whatever type the complaint originally assumes, its tendency is always to revert to that state, and most seldom to exceed it. We do not find, for example, the lower varieties of ichthyosis, however modified they may be by external causes, attain a higher or more advanced grade; nor, on the other hand, does partial ichthyosis pass into a more general form. I would also mention that scarcely a single case of ichthyosis has passed under my notice, unattended by a peculiar malformation of the external ear, and notably of its lobe, which might be taken as no mean exponent of the degree of the primary disease involving the skin. My attention was first directed to this inquiry when examining a harlequin fetus, in which no trace of an external ear remained; and, in proceeding through successive deviations from this example, a corresponding diminution in the extent of malformation was observed, until the opposite limit was reached. The only apparent alteration then consisted in the lobe being connected with the adjoining surface of the cheek, of which it seemed to constitute a part.

Allusion has been already made to the complication of ichthyosis with prurigo: that with eczema will demand a few words. The occurrence of eczema, although sufficiently rare, is chiefly found in ichthyosis when the latter is partial. In some instances, the eczema, if slight, would seem to be accidental; but I am disposed to conclude that in the greater number the complication should be regarded as congenital, returning as it mostly does in the course of a few months from the date of the original disorder, and with an inclination to harass the patient more or less afterwards. At first, it is the face or sculp which commonly suffers, and then the complaint spreads to other parts, as the neighbourhood of the larger joints; and thus we find that, while the outer aspect of the extremities is uniformly rough and harsh, the inner surface is studded with eczematous patches. These vary in degree at different periods; but seldom, under the most favourable circumstances, is the skin wholly free. Sometimes the eczema developed in ichthyosis is due to syphilis, which may be delayed in its outward manifestation until the second or third year; later than this, no instance has come under my knowledge. Such cases are amongst the most severe in all that concerns the extent of the eruption and the attendant irritation. As a rule, they are unaccompanied by loss of flesh or syphilitic cachexia.

Among the occasional accessories of ichthyosis, for the name of complications they hardly deserve, may be mentioned an undue escape of the lacrymal secretion. This happens in those cases where, from the rigidity and consequent retraction of the skin of the cheek, the lower lid is everted. Another, and a more common attendant, inasmuch as it generally selects the milder examples, is the occurrence of coryza, and with it an inflamed condition of the Schneiderian membrane at its lower part. The coryza is often easily provoked, and may continue unchecked throughout the winter months. Again, the subjects of ichthyosis are more than others liable to bronchitis or catarrh, or they suffer habitually from cold to a far greater extent than ordinary persons. On the other hand, where no apparent outlet is afforded in any portion of the skin, the extreme of heat is still more dreaded in certain instances, although they

happily constitute a minority. It is not mere exposure to the sun's rays, or any kind of extraneous warmth, which awakens this burning sensation in the skin, once forcibly expressed to me by a patient upwards of seventy years of age, who had had general ichthyosis, I need not add, all her life, or nearly so. The heat of summer alone is enough to induce it.

There is a species of so-called ichthyosis to which the name of *spurious* has been given by some writers. It is a product of the sebaceous glands, and has no connection at all with the disease under review. In another kind, *ichthyosis cornea*—as remarkable as it is rare—I must refer the reader to what I have elsewhere mentioned on this subject. The name would seem to have originated from a tendency often noted in this disease to produce excrescences on various parts of the affected surface which, by their increase, become developed into horns.

The prognosis of ichthyosis, in its several varieties, is unfavourable as regards complete or permanent relief; but the complaint is nevertheless in most instances greatly amenable to treatment. After a time, the skin becomes smooth, and scales are no longer renewed—a source of no slight satisfaction to the patient. The malformation, however, in any case remains; and with it a disposition to the return of the disease, which may be provoked by many causes, such as exposure to atmospheric changes, or the neglect of precautionary measures; and it is to the non-fulfilment of the required conditions, in so far as they relate to the general health and the state of the skin, that a relapse is mostly attributable. I have known ichthyosis successfully relieved, and to such a degree, by the warmth of summer alone, that during the season it could scarcely be said to exist; but, with the approach of winter, its true character never failed to be declared. In this class, which may be said to be restricted to the less serious cases, and only a particular section of them, there is no doubt that a removal to a more genial climate than our own would be followed, for the time at least, by a tolerable exemption to the patient from his complaint. I have now under observation, in the private practice of Mr. Startin, a boy aged 11 years, the subject of ichthyosis, who is a singular exception to a very general rule in this disease, inasmuch as in the summer months he derives the greatest benefit from a residence at the seaside, and even from bathing in the sea. The first example of ichthyosis recorded at the commencement of this paper is a notable instance of how much may be gained by remedial measures properly applied, the patient being enabled to return to her ordinary duties as a domestic servant with comparative comfort as regards the cutaneous disorder, thus kept in abeyance. In the milder cases, in which, although general, the limits of pityriasis are scarcely exceeded, much, and at the same time more lasting, benefit will likewise accrue from remedial agency; and the same applies with equal, if not greater force, to ichthyosis in its partial form. In that kind, which is distinguished by the extent and thinness of the scales, and where the surface partakes more or less of a reddish tinge, the probability of even marked improvement, in my experience, is remote. In these, the severity of the disease is less determined by the size and thickness of the cuticular products than by the general completeness of the complaint; and of this we have sufficient proof in the exposed mucous lining of the lower eyelids and the lips, as well as in the malformation of the external ear. There is also much liability to exacerbations and remissions, a sense of aching and burning generally preceding an attack. The fingers are then apt to contract in the flexed position, and likewise the elbows and the knees. As a consequence, transverse cracks speedily arise over the phalangeal articulations, or fissures form at the side of the elbow or the neck, or on the loins. While this condition lasts, the patient's distress may be imagined from the very helplessness it entails; and I am acquainted with such a case, in which, during an attack, the patient cannot move in bed or feed herself without assistance.

Treatment.—In the treatment of ichthyosis, local measures will be found of great service. Our first endeavour should be directed to get rid of the scales, and to render the skin as far as possible soft and supple. This is best accomplished by the aid of glycerine, a valuable agent in many diseases, as was first pointed out by Mr. Startin, who introduced it to the notice of the profession many years ago. Unlike

other greasy or fatty compounds, it is readily miscible with water; and hence its efficacy in removing, or at least in diminishing, the excessive dryness of the skin in ichthyosis. It may be turned to account in several ways. As a bath, in the proportion of six to eight ounces to thirty gallons of water, and at a temperature of 94 to 96 deg., it will prove most agreeable, and may be resorted to two or three times a week. Although it signifies little at what time of the day the bath is employed, I generally advise its use in the afternoon or at bedtime, as at the latter period it mostly secures a good night's rest; and in winter particularly, with proper precautions, the patient runs little risk of catching cold afterwards. The high price of glycerine is, however, often a bar to its use in this manner, from the frequency of repetition it entails; and it will then be enough for the patient, after taking an ordinary warm bath, to sponge the whole surface with a quart or more of warm water containing two or three ounces of glycerine; or he may use the latter undiluted, while the skin is still wet. This last is not only an economical mode of employing glycerine, but it is one of great service, as thereby much of its greasy character is lost, while the skin retains its pliability for several hours. In many cases, the bath is impracticable; in such, the patient should be told to grease the surface with an ointment containing camphor and glycerine—ten grains of one and sixty minims of the other to each ounce of lard. This is to be applied with a fold of flannel, and any excess removed by the same means. Sometimes, in lieu of an ointment, castor-oil is preferred; while any objection to its odour is readily obviated by the addition of a few drops of oil of bergamot or bitter almonds.

When the scales are very thick, and not readily removed with friction or soaking in warm water, a piece of pumice-stone will often assist in detaching them, or the use from time to time of glass cloth, such as is employed for polishing. The thickness is most marked in ichthyosis of the palms of the hands, or when it appears on the foot or around the heel.

As regards the general health, tonics, especially those containing steel, will be commonly indicated; and of these none are better than the sulphate and the perchloride. These it is, in most cases, advisable to combine with an aperient, from the tendency they naturally possess to produce constipation. The diet should be nutritive, consisting largely of animal food, and at the same time plain.

While the above remarks were passing through the press, an opportunity has been afforded me of observing a rare example of ichthyosis cornea. The affected surface comprised the greater part of the skin covering the right clavicle, the elbows, knees, and ankles; also the backs of the hands, including the digits. In these localities, the skin presented a smooth, almost glistening, appearance, and was, moreover, of a yellowish hue. It had lost its natural elasticity, and felt indurated to the touch, like a piece of cartilage, from the subcutaneous tissue being likewise involved, and adherent above. There was contraction, in the semi-flexed position, of all the fingers—more evident on the right hand than the left, from its longer duration, and evidently produced by the same cause. A similar state existed on the toes.

The patient I refer to is under the care of Mr. Startin, whom she consulted for the first time, June 1870. Her age is 47. The catamenia ceased two years ago, when the above complaint commenced on the chest; and since then it has appeared in other and distant parts. There is no lack of perspiration generally; but she suffers much from exposure to cold, particularly in the extremities. Pain is felt chiefly over the knuckles and in the feet, especially along the plantar fascia; and so severe has it become of late as to occasion much difficulty in walking. There is no evidence of the affection being at all hereditary.

The extreme infrequency of this form of skin-disease, described by French writers as *aclerema*, must plead my excuse for thus placing it on record. So nearly does it correspond in many essential points to a similar case described by Willan in his work, page 209, that there is no difficulty in recognising it as an instance of what this close observer has been pleased to call ichthyosis cornea. In all that concerns, however, its more obvious characters, as well as in the free perspiration of the surface generally, and the development of the complaint at a so-called critical period of life, it is distinct from that class which, in its several grades, I have ventured to include under the common term ichthyosis. Indeed, its sole claim to the latter designation rests on the horny state of integument, which has already occasioned permanent flexure of the digits, and threatens, unless checked, to lead to more extensive results.

Order 8. TUBERCULA.

Acne is generally described as an eruption of pimples or 'vari,' situated on the face, neck, or shoulders; very chronic in their course, and ending in resolution or imperfect suppuration. A more extended signification than this may, however, be given to it. Thus, it may imply simply an increased secretion of the sebaceous follicles, or their inflammation; or we may have, superadded to the ordinary eruption, a varicose condition of the cutaneous capillaries, with or without hypertrophy of the skin.

Acne commences at and after puberty, and rarely shows itself as a primary affection beyond middle age. It is one of the most frequent complaints incidental to the young adult of either sex. The peculiarity of the eruption, the state of the skin itself, which from the activity of the sebaceous glands often has a greasy aspect; the numerous black points at the extremities of the follicles; and lastly, its locality, render the diagnosis of *acne* in most cases an easy task.

The varieties of *acne* are the following:—*acne simplex vel punctata*, *acne indurata*, *acne rosacea*, *acne sebacea*, and *acne syphilitica*.

Acne simplex is distinguished by an eruption of pimples, varying in size from a pin's head to a pea, and scattered over the upper part of the body. In some cases it is limited to the face—the forehead, nose, and cheeks being mainly attacked; or it may at the same time appear on the sternum, or the shoulders, or between the scapulae; and in the last situation, by no means an infrequent one, its existence is often not detected by the patient. The pimples are hard, shining, and red. They arise in successive groups, and each pursues for the most part an independent course. Often they may be felt as little knots or tubercles embedded in the skin, while the larger and more prominent are observed in various stages of development. Among some of the earlier pimples, after a few days, little yellow spots may be frequently seen at their summits, indicating matter beneath; but if this be let out, only a drop or two of pus escapes, and the size of the pimple is scarcely diminished. It retains for a considerable time its hard circumference or base, and changing in some cases to a darker colour, as in *acne indurata*, slowly disappears. Many of the pimples do not suppurate at all, and in others the pustular stage is delayed for several weeks.

Interspersed with the eruption just described, and indeed noticeable in most of the varieties of *acne*, may be seen numerous black points or specks. These are the apertures of the sebaceous follicles, loaded with secretion, and rendered black from exposure to the air. Besides occupying some portion of the face, or shoulders, they may be frequently observed in the external ear, and as a rule are hardly raised above the level of the skin. Popularly denominated 'grubs,' they can generally be dislodged by the aid of slight pressure applied to the margin of the speck, when a cylindrical mass is squeezed out, composed chiefly of sebaceous matter, besides containing in many instances a minute parasite, the *acarus folliculorum*. It is not uncommon for two or more follicles to inflame and unite, and so produce a good-sized pustule; or the same may occur to a single follicle. These changes are often noticed in the course of the disease, even when advanced towards recovery; and should the complaint be severe, small boils will sometimes be found in adjacent portions of the skin.

In *acne indurata* all the above symptoms are aggravated, and the disease is more-over distinguished by an indurated state of the pimples, and their confluence in lines or furrows. It is usually declared at a later age than the preceding variety, and is most frequent between the twentieth and thirtieth year. In its progress it is remarkably slow, and oftentimes occasions great disfigurement, which is apt to be increased by the accession of furunculi. The latter are less prone to suppurate than in other kinds of *acne*, and are commonly oval in shape, and of a reddish colour; that these contain pus we have sufficient evidence by the thick and yellow secretion which escapes when a puncture is made into the swelling. As recovery ensues, the apertures of the follicles long remain distinct enough to be plainly visible, while the pimples retain a livid or purple base.

Acne rosacea is more allied to erythema, and differs in many respects from the former varieties. When witnessed in early life or at puberty—not that it is commonly a disease of early life—it is sometimes severe, involving the greater part of the face, to which it is always confined. At this age, and particularly when occurring in the male, it is often hereditary. In the great majority of instances, *acne rosacea* is an affection of middle life, and in women is frequently worse just before the catamenia. The redness, from which its name is derived, is at first perceived only after meals, and limited to a small patch, usually seated on the nose or cheek; by degrees it becomes permanent. It is less observable in the morning, but assumes a brighter tint towards evening, and is increased by hot drinks, as tea or spirituous liquors, or by excitement or exposure, especially if the patient should afterwards enter a heated room, or approach the fire. Pimples, around the base of which the colour is always intensified, spring up, indolent in their nature, and tedious in attaining maturity; sometimes at the summit of these a yellow spot is seen, denoting suppuration beneath; or small blind boils become visible, particularly on the cheeks or chin. In many cases, and the more so as age advances, numerous dilated capillaries are seen in or just beneath the skin, arborescent on the cheek, while on the nose they are often longitudinal in direction. The complaint after a time loses its transitory character, and, peculiarly liable as it is to relapse, becomes confirmed. The skin no longer glides beneath the finger, but with the subcutaneous tissue becomes hard and thickened, and finally that hypertrophied condition is beheld which betrays the disease in its ultimate stage.

Acne rosacea is sometimes due to syphilis. It is then noticeable for the crimson flush, which commonly forms a continuous patch extending over the greater portion of the nose as well as the adjoining surface of the face. Developed upon it are small red tubercles, shining and semi-elastic to the touch; they are chiefly situated on the lower end or towards the side of the nose, and also on the cheek; when on the decline the redness vanishes, and although the tubercles may be scarcely recognised, their remains can still be plainly felt with the finger. The affected part is in no degree painful. It lacks the burning or smarting feel which so often attends *acne rosacea*. In other cases syphilitic *acne* has no fixed seat of election. When the pimples around it suppurate, small brown scabs are formed, and a minute ulcer is left at the apex. After this has healed, a depressed and circular cicatrix is left, around which a darkened or copper-coloured areola lingers for a long time. Another symptom indicative of syphilis is the absence of that oily secretion which is so general an accompaniment of *acne*.

Acne sebacea, although described in detail by most foreign authors, is sparingly alluded to by our own. I shall principally follow Hardy in his account of this affection, which, rare in this country, first attracted the notice of Biett. It is described as occurring in three forms—*acne sébacée fluente*, *concrète*, and *cornée*. In the first of these, the sebaceous matter is in a fluid state, and constitutes an unctuous covering on the surface of the skin. The secretion is unattended by pain or itching, and is often abundant. It occupies the same situation as the other varieties of *acne*, and is generally intermingled with them. In the second, the fluid concretes into a scab, varying in extent, sometimes occupying a large space, and in colour ranging from a light to the darkest hue. In consistence the scab is soft and easily moulded, and in recent cases removed with ease. Although similar in locality to the preceding, it sometimes appears on the scalp, and Rayer relates a case of *acne sebacea* of the scrotum. The last, or the *acne sébacée cornée*, is identical with the ordinary sebaceous tumours. (Hardy, *Maladies de la Peau*, folio 100: 1858.)

Various opinions have been expressed with regard to the causes of *acne*. The subjects of it, if young, are in otherwise good health. Unripe fruit, or great indulgence in beer or spirits, or insufficient diet, will produce it; and in girls it is commonly associated with irregularity of the menses; venereal excesses may give rise to it, and there is little doubt that some of the worst instances of *acne indurata* are occasioned by masturbation. *Acne rosacea* is sometimes hereditary, and in those who are thus by nature predisposed, the disease is readily induced by any

excess at the table, or even exposure to cold and wind ; or it may be derived from artificial heat, as in cooks, smiths, and that numerous class who are constantly exposed to vicissitudes of temperature. The origin of the term '*rosacea*' might almost seem to imply its limitation to those accustomed to deep potations of wine or other fermented drinks. But the complaint has no such exclusive restrictions, and even the most temperate are not exempt from it. *Acne rosacea* is apt to occur in women, when the catamenia are about finally to cease, as also in persons who suffer from hæmorrhoids or chronic disease of the liver. There is an eruption that I may refer to, which is sometimes produced by the bromide of potassium, taken internally and in large doses. Although it might be mistaken for acne, it more approaches *impetigo sparsa*, in its pustular character and occasional development on the scalp. It is a rare complaint, and one *sui generis*, as strictly speaking it exactly resembles no other form of cutaneous disease.

With respect to recovery, much will depend upon the duration of the complaint, and in no case should the patient be led to expect a rapid improvement. In *acne indurata* of a severe kind, a long period will sometimes elapse before any decided benefit is gained, and the same applies to *acne simplex* or *punctata*. Still, in any of these forms, as well as in *acne rosacea*, unless the latter possesses an hereditary tendency, a favourable issue may be anticipated.

Treatment.—In considering the different agents for the treatment of acne, we must be guided by its cause, continuance, and variety ; and where there is sufficient reason to attribute it to any error in diet, or to amenorrhœa or other influences, the general state of the health should be regulated accordingly. The diet should be strict, and beer, or acid fruits, or salads especially avoided. If the long accustomed stimulus of alcohol has been suddenly withdrawn, it will be advisable to return to it in moderate quantity. The internal exhibition of steel and the addition of a purgative will commonly fulfil the requirements demanded by general treatment. Arsenic is seldom necessary in *acne punctata* or *indurata*, and not at any time in the other forms.

Local measures play no unimportant part in the treatment of acne ; but care is required that they be not too stimulating. A lotion containing from two to four grains of the bichloride of mercury to eight ounces of rose-water, with the addition of half an ounce of rectified spirit, will prove useful ; it is improved by the addition of half a drachm of dilute nitric acid. Sulphur is also serviceable in acne, and may be used in several ways ; employed in a lotion it should be largely diluted. In other cases a lotion of bismuth answers extremely well in combination with mercury ; one drachm of the trisnitrate, five grains of the bichloride, a drachm of spirit of camphor and eight ounces of water. Among ointments I may mention those composed of mercury or sulphur, which are to be lightly smeared over the parts once in twenty-four hours, and that at night before the patient retires to bed.

Before applying any of the above preparations, the patient should make use of a rough towel dipped in water as hot as can be borne, and thus by opening the pores of the skin cleanse the surface of any sebaceous matter that may have collected. In *acne punctata* he would also do well to rid the sebaceous follicles of their overcharged contents by making pressure at their sides with the finger-nail, when a little cylindrical yellow mass will escape. Any small pimples already on the verge of suppuration should be opened with the point of a lancet, or if of larger size, touched with the acid nitrate of mercury. To remove or diminish the increased capillary secretion, when this exists in a marked degree, various means have been devised. Among the best is strong nitric acid, painted over the part with a fine glass brush, and then immediately absorbed by blotting-paper. In the course of a few days the capillary vessels will be seen to be considerably diminished in number as well as in size. A repetition of the same acid may be employed to any spot that has not already showed signs of disappearing. When acne invades the chin, the latter is apt to become sore and painful. Nellyn suggests in lieu of soap for those who shave, a saturated solution of the bicarbonate of soda, and an equal quantity of olive oil.—G. N.

Molluscum is characterised by round elevations, varying in size from a hemp-seed to a large currant or a hazel-nut, with a dark point and a depression on the summit of each. They have rather a translucent appearance; the colour of the skin over them is either normal or pinkish; occasionally there is a slight lobulation in them, visible through the skin. Some of the growths have no central depression and no black point. Some have a broad base (m. sessile), whilst others have a peduncle (m. pendulum). The skin over them is usually tense; it is occasionally wrinkled. These tumours either increase slowly in size, without any other change, or they ulcerate on the surface and their contents escape, or they inflame and slough *en masse*. They have been commonly believed to be sebaceous glands hypertrophied and altered. Some of them contain a white waxy or semi-fluid material, and a cyst which in some cases consists of several sacculi opening into a common cavity. Under the microscope are seen oil-globules and epidermal cells filled with granular matter. Others are more fibrous in structure. Dr. Beale¹ considers molluscum due to an alteration of the structures concerned in the formation of the hair, especially of the cells at the bottom of the follicle and the follicle itself, with hypertrophy of the subcutaneous areolar tissue.

Dr. G. Simon² describes two forms of the disease; one, which he calls *molluscum simplex*, he describes as due to an extra formation of connective tissue without any change in the hair-follicles or sebaceous glands; and the other, which he calls *m. contagiosum*, he regards as due to hypertrophy of the sebaceous glands.

It seems probable that there are two distinct diseases (both called molluscum) which present very similar naked eye appearances, but are anatomically quite different.

Bateman, Cazenave, and others, used the term *molluscum contagiosum*; but most recent observers do not believe in the contagious character, and drop the epithet '*contagiosum*.' M. Hardy states that he had not believed in the contagiousness of the disease till within the last few years, during which he has seen instances of what seemed to be evidence that it could be thus propagated. He thinks that this property is to be explained by the presence of branched tubes containing the spores of a cryptogamic plant, which he believes are constantly to be found in the tumours of molluscum. Professor Hebra, on the other hand, has tried to propagate the disease by rubbing the contents of the tumours on different parts of the skin without any result. The usual seats of molluscum are the trunk (either back or front), the neck, face, and scrotum. It is not attended with any constitutional disturbance. It may exist at any age, but is most commonly met with in children.

Treatment. - This is purely local. The tumours may be laid open, and the interior rubbed with lunar caustic. If attached by a pedicle, they should be snipped off and the base cauterised.

T. H.

Lupus.—The chief characteristic of lupus is its devastating tendency. Wherever situated, the skin is there destroyed, and finally replaced by a permanent cicatrix. It is, however, by no means limited in its ravages to the skin; sometimes it occasions an utter obliteration of the features; in other cases it ends in a loss of cartilage; and in more rare instances of bone. Generally of tubercular origin, it may be succeeded by ulceration of a most active or else of a most indolent kind; or, again, no ulceration whatever may be observed throughout. Never contagious, and seldom hereditary, situated commonly on the face; disposed to bleed from slight causes, and almost always aggravated by exposure; lupus, from its diversity, is not easily described in exact terms. Lupus may be said to admit of the following divisions: Tubercular lupus, strumous lupus, exedent lupus, syphilitic lupus, impetiginous lupus, and erythematous lupus.

Tubercular lupus is strictly a disease commencing in early life, for the most part

¹ *Path. Soc. Trans.* vol. vi. p. 313.

² *Die Hautkrankheiten*, &c. Berlin, 1851, pp. 235, 354.

appearing between the ages of two years and seven, and seldom primarily developed beyond the period of puberty. The affection is usually represented by a number of distinct tubercles, forming an isolated patch, and disposed on some part of the face, as the cheek or nose. The tubercles are of a reddish hue, slightly flattened at their summits, and in size ranging from a rape seed to a split pea. Their colour is modified by circumstances, and although at times pale, it is generally heightened by such agents as mental excitement or the warmth of a heated room. Beginning as a tubercle, frequently no larger than a pin's head, the complaint may remain stationary for months, ere it exhibits any signs of increase. At length enlarging at its circumference, it presents an irregularly flattened surface, slightly elastic to the touch, of a dull or imperfectly red colour; and bounded by a well-defined margin, which in the direction of its growth is studded with smaller and similar deposits. Sometimes crusts, not unlike those of eczema, may be observed upon it, which if forcibly removed are followed by bleeding, and even by ulceration, or the same result may happen from a blow; but if undisturbed, ulceration does not occur. In other instances, scales rather than crusts are formed of the thinness of tissue-paper, adherent in their centre, and curled and white at their edges. Under treatment the tubercles disappear by interstitial absorption rather than by ulceration, and leave in their room small white and indelible cicatrices. Sometimes the patch, level and of a whitish hue in the middle, shows at its border a number of irregular tubercles; or its whole surface is prematurely smooth, mottled, and dotted with tortuous capillaries. Seldom at any time of its career is tubercular lupus attended by pain. It is a source rather of discomfort than of distress to the patient, whose health continues unaffected. Associated in a slight majority of cases with struma, as proved on inquiry into the history, although not often evincing any of its external signs, tubercular lupus exhibits a slowness in its progress unequalled by any other variety; and it is not infrequent to find the disease, originating as just described, after the lapse of twenty years and more, not exceeding in diameter that of a crown piece.

Commencing like a small boil, *strumous lupus* is distinguished by a tendency to pass into a state of superficial ulceration, unaccompanied mostly by pain. The sore thus established does not easily close. Sometimes it is all but healed when ulceration breaks out afresh, and the same process is repeated again. It is not so destructive as the exedent variety, and pursues its serpiginous course with slight progress for years. When a part has healed for a considerable time, the central portion will in many cases be smooth and dull white, firm, and quite devoid of all natural resiliency. In other cases, the greater part of the surface appears more or less glazed, with a few thin yellow crusts upon it, concealing a number of small and superficial ulcers; or the disease, soon after its origin, may lie dormant for a long interval, and then give rise to a circumscribed sore covered with a scab. Such is the varied course which strumous lupus may assume. When seated on the cheek, which it is in most cases, eversion of the lower lid sometimes takes place from the contraction of the cicatrices, and exposes the mucous membrane of the conjunctiva; and hence a constant overflow of its secretion, to the annoyance of the patient; or beginning on one cheek, the complaint may pass ribbon-like beneath the lower jaw to a similar spot on the other side. Another situation not very uncommon for strumous lupus is the back of the hand or the forefinger; and it is more usual on the upper than the lower extremity.

The *exedent* is the most frequent variety of lupus. Taking rise as a small hard tubercle, it merges after a variable period into the suppurative stage, and becomes covered with a scab. The disease may be circumscribed and limited to a single spot. More commonly other tubercles appear in the immediate vicinity, which pass through a similar stage to the first. When situated on the nose, for which *lupus exedens* seems to have a special predilection, a number of crusts may generally be seen to involve its lower part, adherent and of a greenish-yellow tinge. Should they be removed, a thin light yellow fluid may cover an excavated ulcer: or in place of any secretion, a red granular surface only is left, which bleeds on the least pressure. So soft indeed is the part, that several of the granulations are often

entangled between the blades of the forceps employed to detach the scab. *Lupus exedens* sometimes attacks the nose from within; its mucous membrane first becomes increased in vascularity as well as swollen at a certain spot, and a small crust is established, which in most cases is picked off by the patient. Ulceration still goes on beneath a new crust, and at length perforation takes place, should the septum be the seat. *Lupus exedens* may exist in other parts at the same time, as on the neck, or little toe, or on one of the fingers, proceeding in its course to the complete destruction of the latter; or it may spread over the whole face and scalp. Sometimes no pain of any kind is experienced; occasionally a sense of itching is felt, worse towards night and generally after meals, or only after certain articles of food have been taken. The disease is almost invariably increased by exposure to cold and wind, and often aggravated at the catamenial period. The consequences of *lupus exedens* vary with its situation and the stage at which it has yielded to remedies. Thus, if treated at an early period, as when on the nose, no visible alteration may remain beyond a slightly indented scar; or in a stage removed from this, the end of the nose may be pointed and irregular; or should the cartilage be destroyed, a smooth and polished appearance is given to that portion which remains. On the cheek, the resulting scar if small in its outline is sometimes of a colour inclining to purple; but, when more extensive or in other parts, the cicatrices constitute white and thickened bands similar to those produced by a burn. When the disease encircles the mouth or one or both of the nasal apertures, they sometimes become contracted as cicatrization ensues. *Lupus exedens* may occur on the upper lip immediately below the septum of the nose, the cartilage of which, as well as the lateral cartilages themselves, soon become involved in one common destruction.

Syphilitic lupus is sometimes manifested by the effects of constitutional syphilis being superadded to the ordinary signs of lupus, particularly of the strumous and exedent varieties. Seldom can any reliable conclusions be drawn from the patient's history. Its situation and its multiplicity should be taken into account. Thus it may attack the forehead or the bridge of the nose, and invade at the same time a great part of the upper extremity. I have seen it occasionally attack the buttocks: a serpiginous or horseshoe form is very characteristic of a syphilitic taint. Sometimes we observe one or several patches on various parts of the body, having a smooth centre but a raised and rugged margin, partially covered with crusts and much inclined to bleed. These patches are not uncommon on the forearm near the wrist; a case in a child of about 8 years of age was under my care at the Hospital, in which the complaint was situated on the calf of the leg. In another and opposite kind, but not the less syphilitic, the disease destroyed the lower part of the nose in a young woman, and the margins were surrounded with dense and quickly-growing tubercles. It is not necessary that the complaint be severe in order to be syphilitic, but it may nevertheless owe its severity to such constitutional taint. The worst case of the kind which has occurred to me was that of a boy aged 13 years, an outpatient of the Hospital, who had been suffering from this complaint ever since he was three years old. The nose became quite destroyed, and the mouth reduced to an aperture scarcely large enough to admit the finger. None but those about him could understand his altered articulation. The teeth were nearly all destroyed, and at a subsequent period he lost his left eye.

Impetiginous or papulo-pustular lupus is a name applied by Mr. Startin to that species of lupus the external characters of which resemble those of impetigo. The disease mostly occupies a considerable portion of the face, either as one large and irregular patch or else subdivided into smaller groups. In any case the suppuration is abundant, and the crusts are yellow and easily separated. The latter are neither curled at their circumference, like those of eczema, nor yet raised, as in porrigo: and if removed are quickly renewed. When the scabs are circumscribed, the surrounding skin is often inflamed, but it still retains its natural elasticity. *Impetiginous lupus* is often engrafted upon struma.

Among the more immediate causes of lupus, the receipt of some local injury is often assigned by the patient as the occasion of its first appearance, and hence its

origin is frequently attributed to a blow or scratch. Sometimes it is reported to have succeeded a severe fright, or other strong mental emotion.

Treatment.—In the local treatment of lupus exedens, when the part is covered as it usually is with a firmly adherent scab, the latter should be removed. In slight cases this is accomplished with a pair of ordinary dressing-forceps; but in the more severe, the scabs or crusts should be previously moistened with rags dipped in hot water, or with a poultice. To the surface now exposed we apply for a few seconds a little cotton or carded wool, to soak up any pus or blood; and as soon as it is thus cleansed, the part should be touched with the solid nitrate of silver, cut, if requisite, to a point; or else painted by means of a glass brush with the acid nitrate of mercury. Sometimes it is expedient to conceal the immediate effect produced by the acid, which is easily done by covering the surface with a piece of red blotting-paper, and then painting the latter with collodion. No interference is to be allowed with the eschar occasioned by the caustic. After it has come away, the surface should be wetted two or three times a day with a weak nitric acid lotion; if it still looks unhealthy, a second application of the acid nitrate of mercury will be required, and may be repeated at intervals of two or three weeks. In other cases, in which, as recovery ensues, a red and granulating surface is left, we may substitute with advantage carbolic acid in the form of a lotion, and this should be applied over the thin scales which have replaced the former scabs. In lupus exedens, and particularly if it be conjoined with struma, cod-liver oil will prove a valuable remedy. In what manner it is assisted by mercury is not clear, but given in combination with this mineral, as half a grain of calomel with opium every alternate night, or three times a week, its efficiency is much increased.

In tubercular lupus, the tubercles should, as in the exedent variety, be touched at their summits with a similar caustic. It matters little which is employed, the acid nitrate of mercury, or nitric acid, or caustic potash; but each should always be of the strongest kind, and never applied over too extensive a surface at one time. Tubercular lupus, as far as I have observed, admits of no other local treatment. The caustic requires to be repeated at intervals, until the tubercles are nearly reduced to the level of the skin; for if allowed to extend deeper, little excavations or pits remain, which should be avoided. The patient should be cautioned that considerable inflammation is apt to follow the use of the caustic agent, whatever it may be, and that three or four days or more will often elapse before it abates. As regards constitutional treatment, cod-liver oil and mercury may be given, as in the other forms.

Although by these means we shall succeed in reducing the tubercular mass to the lowest point of which it is capable, and sometimes to such a degree as to render what was before an unsightly object now scarcely perceptible, it should be remembered that the tubercles are very likely to form again, and this tendency must be accordingly corrected. In no kind of lupus is the tendency to recur more frequently shown than in the tubercular variety.

In strumous and in the papulo-pustular lupus, when the suppuration is free, and the ulceration superficial, an arsenic and calomel caustic¹ will be most useful. Sometimes in children this is too stimulating, and calomel alone is the better application. These cases are seldom able to bear the more severe caustics; they are more likely to improve, as well as the syphilitic lupus, should the ulcerated surface be extensive, by the application of a weak nitric acid lotion and the trisnitrate of bismuth.

Plastic operations for the restoration of the nose from lupus have been performed within the last few years by Mr. Hamilton, of Dublin. Time, however, furnishes the only safe ground on which to base our conclusions as to their success. Tried by this test the final issue, even in selected instances, has not been such as to lead me to anticipate a hopeful result from operative interference. In all cases of this kind we have diseased tissue to deal with, and hence sloughing of the part is a likely contingency—an event which mars the best operation; for unless union takes place by the

¹ It is made thus:—*acidi arseniosi*, gr. iij.; *hydrargyri bisulphureti*, gr. ij.; *hydrargyri chloridi*, xj. The powder is made into a paste with water, and applied with a camel-hair brush after the scab is removed.

first intention, the condition of the patient is rendered worse than before. Again, there is often great difficulty in forming a proper septum, which, should the disease return, is almost sure to be destroyed. But the strongest objection is to be found in the fact that the new structure has finally dwindled or degenerated, after apparent success has at first been gained.

Sometimes we are called upon to repair the ravages produced by destruction of tissue in the lips, over which the saliva is always dribbling. In such a case our first endeavours should be directed to promote cicatrisation, an obstacle to which is often to be found in an offending tooth. A well-marked case of this character was that of a man advanced in years, and who had long been an out-patient under Mr. Startin. After the surface had healed, an attempt was made to supply the deficiency of the lower lip, which was almost wholly destroyed, by an artificial one formed of gutta percha and afterwards stained of the natural colour of the skin. This was attached by either end to an elastic band, which passed round the back of the head and served to keep it in position. By the aid of this simple contrivance the patient could partake of his food with comparative comfort. He was also able to resume his work as a gardener, without being subjected to those personal annoyances which his former disfigurement frequently gave rise to.

The subject of *erythematous lupus* has received so little attention from writers on diseases of the skin, that I shall offer no apology for dwelling at greater length than usual on this not uncommon variety.

Erythematous lupus is not a complaint of childhood, and is extremely rare before puberty; it pertains rather to middle life. The influence of sex is remarkable, and the frequency of its occurrence in the female in comparison with the male may not be unduly represented at eight or ten to one. Unlike other kinds of lupus, the erythematous is met in the higher equally as in the humbler ranks of society; occupation, indeed, would seem to have little power in its primary manifestation, however it may affect the issue, as in those callings which demand continued exposure, whether to extreme heat or cold. Again, erythematous lupus is commonly associated with good health, and as an affection of the skin it occurs alone, being seldom attended or followed by any other cutaneous complaint. Lastly, the disease is in no degree hereditary, nor, I may add, contagious.

The earliest sign of the eruption is in general denoted by an erythematous patch on the face, usually the cheek, but it may be the nose or forehead, which, at first only temporary, becomes afterwards permanent. When the patient has what is called a high colour, the preliminary redness is sometimes scarcely noticed, while in an opposite class its occurrence is at once observed; in many instances, before assuming a persistent character, it appears only at a particular time, as, for example, in the summer months, and again returns during a like period for two or more consecutive seasons. There are now developed, on or near the centre of the patch, small white scales, which increase in number until they approach its edge, where a clearly defined border is left. The scales occur in two forms, either as scurf or as a crust, but in either case they closely adhere to the surface.

The former of these varieties is the most frequent, and as a rule is accompanied by a sense of heat and itching in the part, particularly if the patient be exposed to a cold wind or the warmth of a fire. It terminates either in a white cicatrix, which as a rule is on a level throughout with the surrounding skin, destitute of scales, and devoid of any hardness; or in complete recovery.

In the second variety the crust, as it may be truly styled from its thickness, is not detached without difficulty from the skin, and when removed, there are seen on its under or attached surface a number of minute projections which dip into the follicles of the cutis, and render more intimate the connection between the two. A further stage consists in the following curious condition, which the part thus affected undergoes. The crust has disappeared, and a peculiar mottling of the skin is left, which may be likened to the dotted surface of the cut rind of an orange or lemon. The period when this takes place varies in different cases: it may commence within

a few weeks of the outbreak of the complaint, or it may be deferred to a much later date. Let it happen when it may, this condition implies a structural change in the skin, which, in my experience, does not admit of a return to its normal state; it approximates to a cicatrix, and to this it at length tends, becoming with age smooth and white, but still elastic.

Although the above may be instanced as the usual types of erythematous lupus, departures from them nevertheless will happen. In some, the crust of which I have just spoken occurs by itself, with no erythematous base, and in this case the part attacked occupies but a limited space. In another class, the scales are so numerous and extensive as to well nigh conceal the patch on which they rest, and give to the complaint an appearance much resembling psoriasis. In a third kind, the disease is seen in a multiple form, and approaches more nearly to erythema with a sparing quantity of scales on its surface.

Besides the localities already named, the disease is sometimes declared on the eyebrows or the lids, and these may even furnish the only evidence of its existence. In the former it is for the most part speedily followed by a loss of hair on the patch, which is seldom, if ever, renewed; and in the latter it generally manifests itself as separate and circular spots, or it may attack either canthus, and thus involve both lids simultaneously. Sometimes along the line of the eyelashes, where the complaint encroaches on this part, a row of small scales will be seen to surround their roots; and in chronic cases, the mucous lining of the affected lid exhibits in one or more places a deeply red spot, while the rest of the same surface shows a brighter hue than natural, or by comparison with that of the other eye. As a sequence, an excess of the lacrymal secretion takes place, which is often the means of directing our attention to the condition of the lid, and so detecting the appearance it assumes. Should the complaint affect the ears, the lobes are commonly the first to suffer; from these it may creep along the whole rim, which in confirmed and chronic instances shows a singular departure from the state of health in the white, rough, and wrinkled, almost sodden appearance it presents. In others, the disease is mainly confined to the back of one or other of these organs, or the front of the concha, from whence it may travel along the external auditory canal, and interfere with the sense of hearing. Erythematous lupus is equally prone to attack the scalp, particularly in or near the middle line, where one or more patches may be observed destitute, as on the brow, of hair; and, if of long continuance, assuming a smooth and perfectly white aspect. Again, the exposed mucous surface of the lips offers another and not at all an infrequent locality; the complaint in this situation being conspicuous for the dry state of the membrane, which is rough from the presence of small and semi-adherent scales; or it may involve the mucous lining of the nostrils, commencing, as is usually the case, on the skin near the septum, and gradually spreading upwards.

Whatever its situation, the tendency of the disease is to spread, and this may take place in two ways, either by an extension of the patch at its periphery, or by the evolution of separate spots, mostly circular in form, in various places on the surface. As illustrating its general course, I would remark that where the cheek, for example, is the subject of this complaint, it mostly happens that sooner or later a similar patch arises on the other side, and these, enlarging at their circumference, approach one another, and spanning like an arch the bridge of the nose ultimately coalesce, forming a sort of mask which envelops the greater portion of the face. In extreme cases, in which erythematous lupus has existed for many years, we may sometimes note at one and the same time, the various phases of development and decline. Not always, however, as if to demonstrate its uncertainty, is erythematous lupus thus progressive. Sometimes the complaint is confined to a solitary spot or patch, which for years makes little appreciable advance.

Although from the chronic nature of the complaint we cannot in severe examples predict the time when its progress will be stayed, or deny the possibility of a relapse, the disease, whatever its form, is largely determined in its course by the following events. In the first list may be ranked anything that depresses the mind, whether care, anxiety, or grief. In like manner exposure to a cold wind is sure to aggravate

the disease, and so will in many cases a too near approach to the heat of a furnace or a fire, or a protracted stay near the sea-coast; not seldom is erythematous lupus associated with leucorrhœa, or some uterine disturbance or ascarides or hæmorrhoids. Even a slight derangement of the general health or habitual costiveness or too much indulgence at the table will occasion a similar result. Some of the worst cases of this affection that have passed under my notice have occurred in those who have been obliged to work daily in the fields, besides subsisting on scanty fare. In these the chance of permanent improvement is slight as long as the above influences exist. In other cases, and particularly when the affection is seen in an early stage, a more fortunate issue may be anticipated. I have already alluded to a multiple form of erythematous lupus occurring on the face, and in this variety the prognosis is favourable.

Diagnosis.—Unlike most eruptions of the skin, it is in its early stage that the difficulty of diagnosis is usually greatest, although in many cases its true character has not been suspected at any time. Nor will this be altogether a matter of surprise, when the comparative rarity of the complaint is considered, or its varying aspect in the same patient, and still more in different instances. In the majority of its symptoms, the erythematous is wholly distinct from the other kinds of lupus, and at no period is it attended by that destruction of the soft tissues or of cartilage which gives to lupus in general its hideous aspect. From its restriction to the skin, and the occurrence of scales on the patches, erythematous lupus may be mistaken for psoriasis; for so abundant is the squamous covering in some cases, that an error on this point may be well imagined. On examination we shall discover that the scales are not accumulated towards the centre, that the progress of the patch, if a solitary one, is in general slow, and the redness remarkable for the abruptness of its margin. The scales are moreover so adherent, that friction fails to remove them. Among other aids to diagnosis may be added the development of the disease after puberty, and its limitation, except in a few instances, to some part of the face or scalp. Again, there are certain species of secondary syphilis, which bear a close similitude to erythematous lupus.

In the variety characterised by the peculiar mottling of the skin to which I have before adverted, a mistake in diagnosis is less likely to arise, and in all instances the co-existence of a similar complaint in such regions as the ears, scalp, or mucous membrane of the lips will be strongly corroborative of the diagnosis of erythematous lupus. Finally I may add that, when occurring only upon the cutaneous surface of the lids, or around the eye, it is frequently confounded with eczema; or if at the eyelashes, or the adjacent conjunctival lining, with tinea tarsi.

Treatment of erythematous lupus. The use of the more powerful caustics is inadmissible in this form of lupus. Should the complaint have made little progress and present a good deal of redness, the patient may apply twice a day with advantage a weak solution of nitric acid. The benefit of this treatment is most apparent when much cuticular desquamation overspreads the patch. Or if smarting pain be felt in the evening, a lotion of borax, a drachm to eight ounces of water, with two drachms of dilute hydrocyanic acid, may be substituted. If the disease be very limited and as yet in an early stage, I have frequently found that blistering the part in the first instance is useful before having recourse to either of the above lotions. In some cases, as when the scales are unusually thick and removed with great difficulty, the arsenical powder applied over them has succeeded in rendering the surface smooth. Internally steel is recommended, to which in chronic cases arsenic may be added.

Cases are related of lupus ending in spontaneous discovery. This is contrary to all I have ever seen of the disease, which, left to itself, instead of inclining towards improvement, is distinguished by an opposite tendency. It may happen that for a while this affection may remain stationary, as in the tubercular form, but it is contrary to experience that the tubercles should of their own accord disappear; indeed, I would rather say, that the degree of relief to be expected or attained in lupus is proportioned to the period at which the remedy is applied, and not to any inherent property the disease possesses to become exhausted or to wither away.

The plan which is sometimes recommended, of treating the disease by constitutional measures alone, as cod-liver oil, and at others by local means only, can scarcely apply to a complaint which differs so much in its symptoms, progress, and issue, and whose course itself is so liable to vary. G. N.

Leprosy, tubercular leprosy, or elephantiasis Græcorum.—Without entering into any argument as to the identity of this disease with that so frequently mentioned in Holy Writ, or described from the earliest dawn of profane history as existing in Egypt, there can be no doubt that if we refer to the records of the fourteenth and fifteenth centuries of our own era, we shall find abundant evidence of its ravages over the greater part of the continent of Europe, and that the inhabitants of these islands were in no way exempt from it. Happily rare among us at the present time, the complaint nevertheless prevails to a great degree in Norway, Denmark, and Greece. In the East and West Indies, the Azores and Madeira Islands, and along the shores of the Mediterranean, it is not at all uncommon. For an interesting addition to our knowledge of leprosy we are indebted to a professional visit paid by Dr. Webster to the Hospital for Lepers at Granada, founded by Isabella, and supported to this day by the Spanish Government. The results of his inquiries are embodied in a paper which was read before the Medico-Chirurgical Society in 1854, and to the facts therein contained I shall have occasion to allude.

Leprosy is much more common in the male than the female. Of 284 lepers who were reported in Spain in 1851, 188 were of the former and 96 of the latter sex; and at the period of Dr. Webster's visit the ratio between the sexes was thirty-five to fourteen. The experience of Mr. Day confirms this statement as regards the greater prevalence of this affection in the male among the natives of Madras. In Bombay, at the Jarnsetjee Jeejeebhoy Hospital, where all classes of natives are admitted, the proportion is still higher than the preceding. In this latter Presidency the disease is well known among the natives; it is not restricted to caste, but affects the Anglo-Indian, Portuguese, Parsee, Jew, Mussulman, and Hindoo. Although comprising two varieties, the tubercular and the anæsthetic, it must be understood that these are frequently united in the same person, and that the latter is often found to merge into the former variety of the disease.

Elephantiasis is comparatively rare under puberty, and it does not often occur after middle life. Its effect in shortening life is variously stated by different authorities. Although it may show itself at any age, yet when it happens before puberty, the general signs indicative of puberty are deferred beyond the usual time; the hair becomes scanty and ill-formed, and the whole frame ill-developed. Moreover, when it appears at this period of life the patient seldom survives beyond a few years.

Anæsthetic leprosy occurs in patches, and is characterised by a want of sensibility in certain parts of the skin. The patches are circular, or serpiginous; sometimes little elevated above the surface; and in size ranging from a threepenny to a crown piece. In colour they may be almost white or reddish, and at the margin of a light brown. They are found on any part of the trunk or extremities; or on the face, as the forehead, cheeks, or lobes of the ears. Sometimes the patches coalesce, in which case a large extent of surface is occupied by the discoloration. It is in their centre that anæsthesia is most marked: not that this sign is confined to the patches; it may extend along the greater part of the trunk or limbs, following the course of one or more of the nerves. The diseased surface is generally dry and wrinkled, mostly destitute of hair, and devoid of moisture. Sometimes the skin of the fingers or toes is shrivelled and covered with exfoliation of the cuticle. In a few instances a pricking pain is first felt, and in some an eruption of vesicles or bullæ is among the earliest symptoms. These soon burst and form ill-conditioned ulcers, which are slow to heal, and secrete an offensive sanies. After the discharge is reduced, the ulcer, although not extending at its circumference, increases in depth, reaching to or exposing the bones. The phalanges of the fingers or toes are in this way attacked, and become attenuated in their centre. Supposing one of the hands to be affected, the patient

loses power over the extensor muscles, the hand drops, and he is unable to straighten it. Although it may extend to the trunk, anæsthetic leprosy does not often commence in this region. It generally proves fatal through the supervention of some exhausting disease, as dysentery or diarrhoea.

Tubercular leprosy is preceded by a variety of symptoms. Sometimes the first thing that attracts the notice of the patient is a numbing pain in the part, or there may be only œdema. More commonly irregular patches are observed, slightly elevated, and of a grey or brownish colour. On these patches are developed small tubercles, which are usually of a red hue. With their multiplication and increase on the face the countenance becomes greatly disfigured. They are often collected near the apertures of the nostrils; or on the upper lip; or on the forehead, which is thrown into large folds; or they may commence on the lobes of the ears. The occurrence of febrile paroxysms is noticed by some authors, during which the local symptoms are aggravated. With their disappearance, and they generally last about three days, the patient feels little uneasiness, and sometimes the blotches disappear. This condition, however, is only temporary, as sooner or later the blotches return. After a time other complications arise, which involve one or more of the organs of sense. The tongue or the soft palate is covered with similar tubercles, which, as they ulcerate, produce a fetid discharge. As the tongue participates, all appreciation of taste is lost, deglutition is with difficulty performed, and the voice has a harsh sound, or is scarcely audible. If the disease spreads to the vocal cords, or the trachea, the patient dies from suffocation. When the nose is implicated, fragments of diseased bone are often intermingled with the pus. Sometimes ophthalmia is induced, which is generally the forerunner of further and destructive changes taking place in the eye.

A difference of opinion exists as to the influence of leprosy on the generative organs. Most modern authors reject the testimony of antiquity on this point, and regard as fabulous the *libido inexplicabilis* recorded by older writers. Dr. Webster confirms the judgment of the latter, relying on the statement of Dr. Alveiro, who for many years filled the post of Superintendent of the Leper Hospital. Whatever may be the effect at an early stage, there is reason to believe that with the progress of the disease atrophy of the testis is far from being an infrequent result.

As to the causes of leprosy, little is known that can be urged with certainty. In the fertile districts around Granada, which teem with an agricultural population, provided with the ordinary requirements of life, the complaint is rare; indeed, it is mostly limited to the sea-coast. The same may be said of its appearance in France, where it is chiefly seen in the southern provinces of the empire. It is uninfluenced by occupation. However free from it the pure English race may be in India, it will attack those of mixed descent in that country and in the West Indies. I am credibly informed that it is not uncommon in the white population who have long resided in the latter colony. In India it is chiefly confined to the poorer classes of the community, but the rich do not always escape. A diet consisting mostly of fish is supposed to be favourable to its development; the disease is nevertheless frequently met with inland, as in the Deccan and the North-West Provinces.

With respect to hereditary transmission, there is no doubt that elephantiasis is sometimes received in this way, more often than the subjects of it are able or willing to admit. As in other hereditary complaints, elephantiasis occasionally passes over one generation to reappear in the next. It is never contagious. It is not known to extend to those whose duty it is to wait on the sick, or who are otherwise brought into personal contact with them. A leper may continue to live with his family for years, without communicating the disease to any of them; nor is he considered an outcast so long as he can toil for his bread, or has the means of supporting himself. It is when his resources at length fail, and he is obliged to beg in the bazars, maimed and mutilated, that he becomes an outcast in reality, and presents a picture of misery to which it would be difficult to furnish a parallel.

Much of the obscurity that long enveloped the morbid anatomy of leprosy has

been dispelled by the valuable investigations of Dr. Carter,¹ who, as surgeon to and curator of the Museum of the Jarnsetjee Jeejeebhoy Hospital, has had ample opportunities of pursuing his inquiries. The conclusions he has arrived at throw an entirely new light on this important point. It is in the altered conditions of the nerves that we must really look for the seat of mischief. To the eye the affected nerve is considerably enlarged, and changed in colour to a reddish grey. On section its funiculi are remarkably firm, but the neurilemma is unaltered. Microscopical examination shows the nerve tubules at the seat of the enlargement to be more or less wasted and atrophied, and accompanied by fatty degeneration. The places at which these characters are seen vary with the nature of the nerve. Another result of the same disease may be mentioned in reference to the bones, as the digits, which after a time undergo remarkable changes, due to interstitial absorption and necrosis. The fingers and toes are sometimes reduced to so many stumps, and in every case the last phalanx is the first to suffer. The bones themselves become likewise lighter and thinner.

Treatment.—Little can be done in the way of treatment. In an early stage, before the tubercles have ulcerated, the complaint is in some cases arrested for a time by the internal administration of mercury, given in a decoction of bark or some other vegetable tonic. The prognosis, however, in any case is very unfavourable.

Elephantiasis Arabum, sometimes styled Cochin or Barbadoes leg, has its seat mainly in the extremities or the genital organs. It has never been a conspicuous disease in Europe. Although its derivation would seem to imply an Arab origin, the complaint is less frequent at the present day in Arabia than in certain parts of India, as the lower provinces of Bengal, and particularly along the coast of Malabar.

So prevalent is elephantiasis Arabin in British Coochin, that Mr. Day,² who for some time filled the office of civil surgeon there, records his inquiries thus:—

In 24 Indo-European families, 1 in 18 $\frac{1}{2}$ affected.

In 71 Native Christian , 1 in 17, ,

According to Mr. Waring,³ the Jews (white and black) in the same locality exhibit a higher proportion, being in the ratio of 1 to 14½ nearly. Besides these classes, elephantiasis attacks, and that indiscriminately, other of the native races of India, as the Mussulman and Hindoo.

In 100 cases, Mr. Day reports as follows:—

	Males	Females	Total
Left forearm	3	0	3
Right lower extremity	17	10	27
Left " " " " " " " "	11	13	24
Both extremities	18	13	31
Both lower and upper extremities	4	0	4
" right upper extremity	1	0	1
" left " " " " " " " "	2	0	2
Both lower extremities and scrotum	1	0	1
Left extremity and scrotum	1	0	1
Right " " " " " " " "	2	0	2
Scrotum	3	0	3
Mammae	0	1	1
	<hr/> 63	<hr/> 37	<hr/> 100

From this table it appears that no less than 93 cases of elephantiasis in 100 are those affecting the lower extremity. A smaller percentage is given by Mr. Waring; thus, in a collection which he made of 945 cases, 307, or 32.49 per cent., belonged to the lower extremity; 287, or 30.57 per cent., to the upper extremity; and 344, or 36.40, to both lower extremities.

Under the age of ten years, elephantiasis Arabum is infrequent. From the period of puberty to the age of twenty-five or thirty years it is generally observed. Owing to the prejudices of caste, it is difficult in India to determine anything like an exact

¹ *Transactions of the Medical and Physical Society of Bombay*, vol. viii., new series, p. 1.

² *Madras Quarterly Journal of Medical Science*, 1880, p. 37.

³ Waring, 'On Elephantiasis,' *Indian Annals*.

ratio of its occurrence between the two sexes. There is little doubt that it is more common in the male than in the female, and probably the proportion of 2 to 1 would represent the nearest approximation. It is not a little remarkable, that while in Madras elephantiasis so much affects the lower extremity, in Calcutta it is the genital organs which are usually attacked. Sometimes the complaint undergoes a kind of metastasis, and leaves the leg altogether, only to show itself in the scrotum or other parts.

[Elephantiasis for the most part commences with erysipelatoid inflammation, attended with febrile symptoms. The parts affected become red and deeply infiltrated; and at the same time the superficial veins and lymphatics generally form red, painful indurated cords, and the corresponding lymphatic glands become inflamed. The tissues at this time are infiltrated with yellowish transparent coagulable fluid, apparently lymph. The inflammation lasts for a few days, and on subsiding leaves more or less swelling and induration behind. Subsequent inflammatory attacks recur from time to time, each one adding to the permanent hypertrophy which is in progress. Thus by degrees the affected parts become largely, sometimes enormously, increased in bulk and altered in aspect. The hypertrophic changes may, however, originate and progress independently of obvious inflammation.

In some cases elephantiasis involves mainly the skin and subcutaneous connective tissue; in some it includes the whole of the connective tissue between the skin and bones. In either case, but chiefly in the former, the skin often undergoes much change of texture and appearance; sometimes it becomes coarsely papular or warty, sometimes studded with nodular elevations, sometimes ulcerated; and the epidermis, though often remaining normal, may desquamate or get thick or horny, or take on the characters of ichthyosis, or become more or less deeply coloured from deposit of pigment granules in the rete mucosum. The surface, moreover, may be anæmic, congested, or livid. When the disease extends deeply, fat, muscles and nerves get compressed and waste; but the bones undergo hypertrophy, new layers and irregular outgrowths forming, and adjoining bones occasionally becoming organically united.

Elephantiasis appears to consist primarily in an inflammatory hyperplasia of the cellular elements of the connective tissue, in connection with which (according to Virchow) there is reason to believe that the roots of the lymphatic vessels are specially involved. Inflammatory overgrowth of the elements of the lymphatic glands next ensues, with obstruction to the passage of lymph through them. Then this fluid stagnates in the lymphatic vessels, which sometimes dilate even to their radicles in the cutaneous papillæ, and accumulates in the interstices of the affected tissues, adding to their bulk, and at the same time stimulating them to overgrowth. It is only in the early stage of the disease that the dilated condition of the lymphatics admits of ready detection. At a late period the morbid tissues are characterised mainly by a dense accumulation of white fibrous tissue. The lymphatic glands also after a time become the seat of fibroid change.

In some cases of elephantiasis, especially those in which the genital organs or adjoining parts of the thigh or abdomen are implicated, groups of vesicles appear here and there on the affected surface, which are really dilated lymphatic spaces, and which on rupturing (as they are apt to do from time to time) discharge considerable quantities (sometimes several pints at a time) of lymph, which coagulates after its escape, and is either yellowish and transparent, or milky from the presence of molecular fat. There is reason to believe that chyluria is due to a similar affection of the urinary passages; and indeed this is occasionally associated with elephantiasis.

Dr Lewis's observations, which have been confirmed by many subsequent observers, show that, at any rate in a large proportion of cases of elephantiasis, as well as of cases of chyluria, the blood contains large numbers of embryonic nematoid worms, to which he has given the name of *filaria sanguinis hominis*. And it would further seem that the presence of filariæ in the blood is due to the presence of one or more parent worms, two or three inches long, lodged somewhere in the body, probably in some part of the hypertrophied tissues. It is supposed that in those cases in which the

filariæ are present they are the cause of the patient's malady, and that they produce mischief mainly by obstructing the lymphatic channels.

The regions most frequently attacked with elephantiasis are the lower extremities and genital organs. But other parts may become affected, and especially the female breast. In the first of these cases the disease usually begins in the toes or about the ankles, and gradually involves the whole leg up to the knee. It rarely, however, rises above this point.

J. S. B.]

The swollen limb is hard and brawny to the touch, and little capable of impression; and is often covered with thick cuticular exfoliations, resembling those of ichthyosis, which decrease in number and size from below upwards. In this state it may remain for years, causing little pain, and inconvenient only from its bulk.

The further progress of the complaint is frequently proportioned to the fatigue the patient has to encounter. As long as the limb is allowed to remain quiet and horizontal in position the increase is inconsiderable, but continued exertion, as standing, aggravates the local symptoms, and the pain, at first intermittent, becomes constant. The limb is greatly enlarged, and also the superficial veins. It is hard, and of a reddish tinge. Should the disease continue to advance, the pain is increased, and ulceration commences at the toes, which are successively destroyed, or large ulcers form on other parts of the foot. Unhealthy granulations occur on the toes, thus reduced to stumps, and show little tendency to cicatrize. In some cases, when the thigh becomes involved, the varicose veins burst, with marked relief for a time to the patient.

When elephantiasis attacks the scrotum, the part becomes hot, swollen, and tender. The pain is not, however, limited to the scrotum, but is felt along the inner side of the thigh and at the groin. The form of the tumour is conical, having its apex above and base below. As the constitutional symptoms which usher in the complaint subside, the swelling decreases to a certain point; and with the recurrence of another attack similar symptoms return, and a corresponding accession is given to the size of the tumour, which may at length reach to the knees. Unless the swelling be great, it usually preserves its form, but the penis is concealed in its large folds. Sometimes the raphe deviates from the middle line, or cracks are seen, from the skin being suddenly and tightly stretched. Abscesses occasionally arise in different parts of the scrotum.

It sometimes happens that during the febrile paroxysm a clear discharge exudes from the skin of the scrotum. This is looked upon as a favourable sign.

Elephantiasis is frequently connected with hydrocele; and in a case that Professor Ballingall¹ operated on, he found, on removing the tumour, that he had inadvertently opened a hernial sac. The swelling in this instance weighed forty pounds, and although the after symptoms were at first severe, the patient perfectly recovered. Sometimes mortification happens, or the skin with the subcutaneous tissue sloughs, exposing the testes. Elephantiasis of the genitals, like the same disease occurring in the lower extremities, is, without doubt, largely influenced by locality.

Treatment.—In an early stage, and when situated in the lower extremities, an attempt should be made to reduce the size of the limb by even pressure. For this purpose cotton or flannel bandages, or, better still, a Martin's elastic bandage, should be applied from the toes and carried beyond the line of the swelling. Ointment containing iodine, or iodine friction, will be also of assistance. The biniodide of mercury, in the proportion of one grain to four drachms of cerate, rubbed into the part, has been productive of benefit, and is recommended by Mr. Day. The first effect of its application, he says, is to occasion some irritative fever, and even an increase in the size of the limb, with more or less pain; but as the latter subsides the swelling diminishes. Combined with this treatment absolute rest is essential. To improve the general health, bark may be given, but no remedy possesses a specific action on the disease. I have known it arrested by the above treatment, and in one case it seemed to lessen from the exhibition of small doses of mercury. How far any

¹ 'On the Operation for Elephantiasis Scroti, with Cases and Remarks,' *Transactions of the Bombay Medical and Physical Society*, vol. viii. p. 232, by Assistant-Surgeon G. Ballingall.

change of climate might prove of service in this country I cannot say, but a removal to a distant station in India, unless the complaint be far advanced, is generally followed by a remission of the local symptoms. The swelling may even disappear, but a relapse is almost sure to arise on the patient's return to his former abode. If this resource prove unavailing, or the complaint occur in a cold climate, the only alternative is amputation at or below the knee. The operation may be safely undertaken in so far as the disease is not likely to recur, and the patient's health warrants such a procedure. In those instances where the thigh is likewise invaded, deligation of the femoral artery has been recommended. It was originally proposed by Dr. Carnochan of New York, and one of the first to adopt it in this country was, I believe, Mr. Butcher, of Dublin. The patient recovered without a single bad symptom, and she was finally enabled to follow her occupation, which was that of a laundress.

The difficulty in tying the artery in such a case is greatly increased by its unusual size, as well as by the risk of wounding, on account of their engorgement, the superficial or the femoral veins. In several cases, the benefit thus gained has been only temporary, and the disease has recurred, with no mitigation of its former symptoms, and after only a few months' interval.

In elephantiasis of the genitals the tumour should be removed. In the native hospitals at Calcutta and Bombay, these growths have been successfully amputated when they have weighed 100 lbs. and upwards.

In one case that came under the care of Professor Ballingall, at the Jamsetjee Jeejeebhoy Hospital, July 20, 1862, he commenced the operation by transfixing the neck of the tumour in the middle line, the knife emerging at the perineum. A strong double ligature was then passed through the opening, and brought up round each side. After tightening the ligatures by tourniquets, the whole mass beyond the testicles was rapidly removed by a double-flap incision. The tumour weighed, after removal, 106½ lbs. The after shock was very great, in consequence of reaction not being properly established for some days, and in consequence of a heavy loss of blood the following day. The recovery was, however, afterwards uninterrupted, and on September 4 the patient was discharged, cured.¹

(G. N.)

Frambesia (yaws).—This is an exanthem rarely, if ever, seen in England; it has, however, been met with in the North of Scotland and in Ireland; it is common in the West Indies and Africa. At the onset there is slight fever, which is soon followed by an eruption of small papules, which increase in size till they attain a diameter of half an inch; the crop of papules is not completed at once; new ones appear whilst the old ones are declining. The eruption is greatest, and the spots are largest, on the face, axillæ, arms, groins, and pudenda. After eight or ten days the eruption becomes pustular, and a crust is formed, beneath which a foul sloughy ulcer is found. On the surface of this ulcer red fungous granulations spring up. These ulcers exist in all stages on the body at the same time, and are often accompanied with ulceration of the throat. The eruption may continue from a few weeks to seven or eight months; after a time the sores contract and cicatrise, leaving no mark unless the inflammation has run high. The disease is followed by much emaciation and debility, and frequently by dropsy. *Frambesia* is transmitted by contagion; it has been communicated by inoculation. It is rare amongst the white races of mankind.

Treatment.—Locally, mild stimulating ointments; internally, tonics, nutritious food, and occasional alteratives; aperients appear to be indicated. Mercurials have been used in former times, but are now generally believed to be worse than useless.

T. H.

Keloid tumours.—The first to recognise keloid growths as a separate class of tumours was Alibert, who describes them as of a reddish colour, sometimes streaked with white lines, not pedunculated, but rather embedded in the substance of the skin. To the touch they are elastic, like fibro-cartilage, and moreover they are not malignant.

Their origin, I believe, is derived from the cutis itself, and not from the subcutaneous tissue, which is seldom implicated. In structure they partake, and that

¹ 'On the Operation for Elephantiasis Scroti, with Cases and Remarks,' *Transactions of the Bombay Medical and Physical Society*, vol. viii. p. 233, by Assistant-Surgeon G. Ballingall.

largely, of the fibrous element, and are highly vascular; this is shown by the number of capillaries ramifying on their surface. The cuticle is sometimes wrinkled, but more generally remarkable for being soft and smooth. There is, in the College of Surgeons, a beautifully injected preparation, which was presented by the late Mr. Edward Stanley.¹ It is an ordinary keloid growth of the leg, resulting from a scald, and extending several inches in the form of a tumour, narrow and not much raised. Its uniformly red surface contrasts with that of the surrounding skin; and, except where it has been removed by ulceration, the epidermis is intact.

Keloid tumours present great variety of appearance. The growth may be confined to a single tumour, smooth, ovoid, and hemispherical; or several of these may be seen at short distances from one another, and in various stages of development. Again, the part affected may be distinguished by irregular but not prominent projections, traversed by numerous bands, or sending out processes or claws in the direction of its growth. As the consequence of a cicatrix, the form of the tumour will correspond to the extent of the primary lesion.

In its early stage the growth is not usually painful, but its character in this respect is often much modified by the health or temperament of the patient. Thus, should there be a tendency to hysteria in the female, or over-sensitiveness of irritability in the male, more annoyance will be experienced from the presence of the tumour than where no such disposition prevails. In many instances no inconvenience is felt, unless the part has been much manipulated, when it itches, or is said to 'burn'; or unless it be constantly pressed upon, as for example when occurring on the scapula in a line with the border of the dress. Sometimes the patient complains of pain, which the least handling increases. At a later period, should ulceration take place, pain is always more or less felt, but it is not determined by the size or growth of the swelling.

Keloid tumours are not limited to any locality. Perhaps they may be said to be most common over the scapula, and next to this over the sternum. Sometimes they show themselves on other parts of the trunk, or upper extremity, or face, but seldom on the lower limbs.

However obscure the real origin of these tumours, a singular predisposition to their production is declared in certain constitutions, whether in the development of new growths or the recurrence of a similar swelling from the cicatrix of one that has been removed. Velpeau relates the case of a lady, from whose breast he excised a tumour of this kind, and who had undergone the operation on two occasions before she applied to him, and again it appeared for the fourth time.² It would be easy to multiply such instances as these. The same liability to return is often observed when, instead of being excised, the mass has been destroyed by caustics, or removed by ligature; and so great is it in some cases that the apertures caused by the needles in closing the wound have shortly become each the seat of keloid tubercles. In one example, which Mr. Longmore lately brought before the notice of the Medico-Chirurgical Society,³ the whole of the back, the greater part of the chest and the face, were studded with keloid excrescences; the only evidence of an exciting cause was afforded by a 'prickly heat,' to which the patient, a soldier, had been exposed while serving in India. The disease was aggravated by the use of the cross-belt, and scarcely, if at all, increased in cold weather. This man never suffered from small-pox or secondary syphilis, and I may add that he was doing duty in the Decan, where prickly heat is far less severe than in the plains of Hindostan. The effect of some injury to the skin is in most cases the immediate cause of a keloid tumour. Among soldiers it not unfrequently follows flogging; in other cases it succeeds gunshot wounds, and particularly burns. The scars of small-pox or rupia, and even leech-bites, have been known to become the seat of keloid tumours.

There is a species of keloid to which Addison has drawn attention, and which he describes as true keloid. How far it merits this distinctive title I am not about to

¹ Preparation 2283 B.

² Velpeau, *On Diseases of the Female Breast*, translated by W. Marsden, M.D., 1856, p. 57.

³ *Remarks on two Cases of Keloid*, by T. Longmore, vol. xlv. p. 105.

discuss; but that the term keloid tumours cannot appropriately apply is, I think, sufficiently evident to any one who examines the models from the originals of which the observations of Addison were derived. Commencing as a white spot, it sometimes spreads in a circular, but more commonly in a linear direction, and in many cases is attended by no elevation of the surface. The skin appears infiltrated, or, to use his own words, 'hide-bound,' and this so far affects the subjacent fascia and muscles as to interfere greatly with their free motion. Generally the skin is of a yellowish colour, and the patch is more or less covered with scales.

Treatment.—In the treatment of keloid tumours we should remember that they are sometimes much affected in their growth by the state of the general health, and that they occasionally disappear. The influence of these conditions should not be overlooked or undervalued, as although the removal of the mass may be readily performed, the risk of its return is always considerable. We may endeavour to promote absorption by painting the part with tincture of iodine, diluted at first, and gradually used pure; or collodion may be employed with a similar object. In one instance related to me by Dr. Broadbent of extensive keloid growths, the latter disappeared or became much reduced from the internal use of iodide of potassium; and in a case of doubtful origin it may be worth while to try the effect of this remedy. The contra-indications to an operation are these:—1st, when the disease shows an inclination to become developed in other parts—in such a case, if excised, it is almost sure to recur; and 2nd, when it has already been so extensive as to preclude any resort to the knife. In these no treatment that I am aware of is of any avail. Rayer, indeed, recommends pressure, but this is more likely to increase than mitigate the evil that already exists. G. N.

Xanthoma, Xanthelasma, or Vitiligoidea.—This peculiar affection was first described by Drs. Addison and Gull under the name of Vitiligoidea. It appears to consist essentially in an overgrowth of fibrous tissue in the true skin and subjacent parts, associated with much fatty degeneration in patches or the deposition of oil in aggregations of minute globules, and with the precipitation of yellow pigment. It has a good deal of resemblance to the atheroma of arteries.

It occurs in two forms, *x. planum* and *x. tuberosum*. The former, which is the more common, affects mainly the eyelids, but also attacks the ears, various other parts of the face, and the mucous membranes. The tuberos form, though occasionally observed in the same parts, implicates especially the flexor aspects of the joints, with the sheaths of tendons, the palms and soles, and other regions of the limbs. The two forms may exist in combination, and may affect between them any part of the surface.

In the plane form of the disease the affected portions of skin present an opaque buff colour, are abruptly margined, and though perhaps looking at first slightly thickened, are really not raised above the level of the surrounding skin. Moreover in softness and pliability there is little or no difference between them and the healthy parts. The affection commences symmetrically in the upper lids near the internal canthus, and thence slowly spreads until in some cases both lids becomes involved in their whole extent.

In the tubercular form, the affection is also for the most part symmetrical. In i papules and tubera arise, varying from the size of a pin's-head to that of a hazel-nut and sometimes by their aggregation form nodulated masses of considerable extent and thickness. These are generally yielding, elastic, and but little indurated, are of the normal colour of the skin, reddish or buff-coloured, and often studded, especially in their more prominent parts, with opaque yellow spots. When occurring in the palms and soles, the papules are generally small, close-set, and give a peculiar mottled aspect to the affected surface. On the wrists and ankles the disease sometimes has a close resemblance to keloid.

Xanthoma is for the part unattended with pain or uneasiness; when implicating the hands and soles, however, it often causes a good deal of tingling or itching. It is usually progressive in its course, but occasionally becomes arrested, and now and then disappears spontaneously. It never undergoes suppuration or ulceration.

It is a disease of adult life, and much more common in women than in men. A large proportion of cases (from one-third to one-half) are met with in association with jaundice, due to organic disease of the liver. Mr. Hutchinson points out that many who suffer from it are liable to megrim. Diabetes has been associated with it in a few cases.

All medical treatment appears to be useless.

J. S. B.

Order 9.—MACULÆ, or PIGMENTARY CHANGES.

These changes are seated in the deeper layers of the epidermis, the so-called rete mucosum. They may be classed under two heads—1, those in which there is excess of pigment; 2, those in which there is a deficiency of pigment.

(1) *Excess of pigment.*—Different races of man exhibit very different amounts of pigment in their skin; the natives of hot climates have much, and those of cold climates little pigment. Developmental changes in the organs of reproduction are often attended with an increased production of pigment; and at the age of puberty there is commonly a darkening of the skin of the sexual apparatus. During pregnancy the areola around the nipple becomes of a darker colour; rare cases have been described in which this discoloration has extended at this period much further, even over the whole front of the body. During menstruation the lower eyelids are often discoloured, sometimes from a sort of venous lividity, in others from real pigmentary deposit. Heat and light have the effect of increasing cutaneous pigment, either uniformly or in spots called freckles (*ephelis*). Yellowish-brown, round or irregular, spots or patches are thus produced on exposed parts, especially in persons of fair complexion. When spots of this kind are more permanent than usual, they are called *lentigo* or *ephelis lentigo*. The skin on the front of the legs of old people often becomes of a brown or liver colour; this change is said to depend on exposure to artificial heat. Many skin diseases leave the skin with an excess of pigment, especially psoriasis, eczema, and prurigo.

Cases are on record in which mental emotions have suddenly induced an excessive formation of pigment; it is more common, however, to see from this cause, in the hair, which is homologous with the epidermis, a loss of pigment. The whole hairy scalp has been said to have become grey in a few hours from intense anxiety or grief.

Dr. Addison first called attention to a peculiar discoloration of the skin (a bronzing), which he connected with disease of the supra-renal capsules; it is accompanied by progressive debility, anæmia, occasional giddiness, and gastric disturbance, and terminates fatally at the end of a few years. The colour of these patients is brownish with sometimes an olive-green tint, and it very closely resembles that seen in the darker races of man. The depth of tint varies in different cases, being most marked in the parts most exposed, and also those in which there is normally an excess of pigment; as, for instance, around the axillæ and near the umbilicus. The pathological connection between the cutaneous change and the supra-renal disease is not very obvious; it has been supposed by some that they are both dependent on irritation of the solar plexus of nerves. It appears, at any rate, to be satisfactorily proved that a bronzing of the skin, accompanied by certain constitutional symptoms, not traceable to any other cause, may be safely assumed as pathognomonic of a peculiar morbid change in the supra-renal capsules. The capsule is first changed into a translucent softish homogeneous substance, which after a time is converted into an opaque yellowish material, and at a later period into a putty-like matter, or a dry chalky mass.¹ Other changes occur in the supra-renal capsules, without pigmentary change of the skin, and on the other hand the skin may undergo discolorations very similar to, if not identical with, those accompanying Addison's disease, without the peculiar constitutional symptoms or disease of the capsules. A case of this kind is described by Dr. Parkes, in which the skin of a man aged 59 years, five months after an attack of jaundice, became gradually dark on the body, arms, and thighs, until the hue was that of the skin of a mulatto; over the abdomen, thighs, and scrotum there were white

¹ Dr. Wilks, in *Guy's Hospital Reports*, vol. viii.

patches interspersed; below the knees the skin was of its natural colour. In this case the supra-renal capsules were found quite healthy; the liver was contracted, and had given rise to ascites. Similar cases are also on record in the Pathological Society's 'Transactions' (as e.g. vol. xii. p. 262); other instances have been met with, in which the skin was mottled with dark and white patches; two such cases are mentioned by Dr. Addison, and considered by him to belong to the same category of supra-renal disease. In one of Dr. Addison's cases, the capsules were diseased; in the other no post-mortem examination was made. Dr. Wilks doubts whether this peculiar mottling, a combination of bronzing with pallor, or *leucopatia*, is in any way connected with supra-renal disease.

Moles (nævi lenticulares, or liver stains) are congenital spots or patches in which there is an excess of pigment.

They are sometimes round, sometimes of irregular shape; and they have either a brown, yellowish-brown, grey, or blackish colour; occasionally they are covered with hairs, which are thicker, stiffer, and darker than the hair of the adjoining skin.

In size they vary from a pin's head to a diameter of several inches. They are either quite flat, or raised above the level of the surrounding skin. There may be one or many of them on one person.

They are formed by an excess of pigment in the deeper layers of the cuticle, which is often thicker than it is on other parts of the surface; and in those moles which project above the level of the skin there is a thickening also of the derma.

They are occasionally the seat of troublesome ulceration, from friction or other cause. In such cases it may become advisable to excise them; and this is the more desirable since they are believed to be often the seat of epithelial cancer in after life.

(2) *Want of pigment*.—This may be congenital and universal, involving not only the skin, but the hair, the iris, and the choroid, constituting *albinism*. Several albinos have been met with in the same family, or one member only of a family is affected. Albinism has been observed to be transmitted by inheritance to one sex more than to the other; in one family preferring males, and in another females. This affection occurs occasionally in all races of mankind, but it is more common in hot than in cold climates. There is intolerance of light, and usually a want of power both in body and in mind.

Partial loss of pigment is also more common amongst the darker races, at any rate it has been more noticed amongst them. Negroes congenitally 'piebald' are by no means very uncommon.¹

Vitiligo is a term differently used by different writers. It is now commonly employed to designate patches characterised by loss of pigment. In some cases there is a slight depression of surface in these white patches, with branny desquamation.

Silver stain.—The internal use of the salts of silver for a long time produces a peculiar livid or slate-coloured tint of skin. No remedy is known for this condition.

Besides the changes of colour above described, there are some rare cases on record in which a free excretion of pigment has taken place on the eyelids; in some cases black, in some yellow, and in others blue. The fluid in which the pigment appears is somewhat unctuous, and the affection has hence been called *stearrhœa nigricans*, *flavescens*, and *cærulea*.² The secretion may be wiped off; but appears again at the end of a few hours. The subjects of these cases have generally been women who have suffered from uterine derangement; some of these changes have no doubt been simulated by hysterical patients. Whether the secretion has come from the sebaceous glands or sweat-glands has not been clearly demonstrated—probably from the former.

T. H.

¹ The pigment is sometimes unevenly distributed, so that there is an excess of it in some parts and a complete loss of it in others.

² Dr. Laycock, *British and Foreign Med.-Chir. Review*, vol. xviii.

Order 10. - PARASITÆ.

Tinea is the generic name of all the diseases of the skin characterised by the presence of vegetable growths in the substance of the hair.

Tinea tonsurans is a very common disease of the hairy scalp, seen almost exclusively in children, and by far the most frequently between the ages of two and twelve years. It is called *Porriigo scutulata* by Willan, *Herpes tonsilens* by Cazenave and G. Simon, and *Trichosis furfuracea* by E. Wilson.

Tinea tonsurans occurs in more or less circular patches varying in size from a sixpence to a crown-piece. All the hairs on the patches appear to have been evenly cut off at about an eighth of an inch from the surface of the scalp. These short hairs are much thicker and more opaque than are the hairs on the other parts of the head, and as the diseased hairs have lost their elasticity they are here and there twisted or bent at an angle on themselves. The surface of this patch is generally covered with numerous loosely attached opaque white scales, and imbedded in these are many opaque, thick, twisted short hairs. When the scaldiness of the patch is trifling, the orifice of each hair follicle may be observed to be surrounded by an opaque white fringe, formed of accumulated epithelium, and the hair-follicles themselves are too prominent.

The patches on which the hairs, &c., are thus diseased are very slightly raised, and are a little redder and hotter than the other parts of the scalp.

Microscopic examination. The thickness, opacity, brittleness, and loss of elasticity of the hairs are seen by the aid of a magnifying power of two hundred diameters to be due to the presence in the substance of the hair of a vegetable parasite. The scales are formed of epithelium, studded with the sporules and mycelium of the same parasite. The plant is the trichophyton tonsurans; the sporules of the plant are found between the inner root-sheath of the hair-follicle and the hair; from this spot the parasite enters the hair; and the mycelium, bearing innumerable sporules, passes between the anatomical elements of the hair, separating them from each other in the most remarkable manner. Passing up from the interior of the hair-follicle to its orifice, the mycelium and sporules spread in all directions among the epithelial scales.

Pathology. Some writers maintain that *tinea tonsurans* and *herpes circinatus* are the same disease. The closeness of the relation between the two is shown by the fact that a patch of *herpes circinatus* seated on the forehead or back of the neck, as not infrequently happens, and extending in size till the upper part of the ring involves the hairy scalp, may retain on the hairless part the characters of *herpes circinatus*, while that portion of the ring which occupies the hairy scalp has all the characters of *tinea tonsurans*; and also by the fact, that in the scales which can be scraped from the surface of the red ring of *herpes circinatus* of the trunk are occasionally to be found some of the mycelium and sporules of the little fungus.

But, on the one hand, a patch of *herpes circinatus* is often seen on the trunk, and occasionally on the scalp, without a trace of the trichophyton to be detected among the debris of its vesicles; and, on the other hand, a patch of *tinea tonsurans* is occasionally seen on the scalp, on and around which no trace of *herpes circinatus* can be found.

From these facts it follows—

1st. That *herpes circinatus* and *tinea tonsurans* are distinct diseases.

2nd. That *tinea tonsurans* owes its peculiar characters to the presence of a parasitic vegetable growth.

3rd. That the secretions of the part of the skin affected with *herpes circinatus* form a favourable nidus for the growth of the parasite.

In *tinea tonsurans* there is first some disorder in the secretions of the hair follicles—a disorder, it may be, attended with no changes perceptible to the eye. If sporules of the trichophyton tonsurans fall on the soil so prepared they take root; the plant grows downwards between the hair and its root-sheath—outwards, upon and among the epithelium of the scalp upwards into the hair, penetrating it, and passing into its shaft. To the existence of the parasite all the visible phenomena are due. Its presence in the substance of the hair causes its increased thickness, opacity, loss of

elasticity, and brittleness. Its presence in and among the epithelium leads to the desquamation of the latter, and, as a consequence, to the abundance of the scales; its presence in the hair-follicles to the swelling of the follicles and to the little fringe around their orifice, and also to the determination of blood to the part. The elevation of the part and its increased temperature are consequent on the flow of blood to it. *Tinea tonsurans* is undoubtedly contagious.

Treatment.—The great object to be attained in the treatment of *tinea tonsurans*, whether the disease be primary or engrafted on *herpes circinatus*, is the destruction of the plant; for so long as the fungus is present, so long will there be increased flow of blood to the part, secretion of a substance favourable to the growth of the plant, and, as a necessary consequence, persistence of the conditions of hair and scalp resulting from the presence of the plant.

How can we destroy or remove the plant? We are acquainted with various agents destructive to vegetable life. The application of any one of these to the diseased patch would no doubt quickly effect our object, were it not for the difficulty of making the parasiticide penetrate into the substance of the hair as low as its root, and pass down to the base of the hair follicle.

Such preparations are the following—bichloride of mercury four grains, lard two drachms; acetate of copper half a drachm, lard four drachms; ammonio-chloride of mercury twenty grains, sulphur ointment four drachms; strong blistering fluid; creosote twenty drops, lard two drachms; carbolic acid 1 part to 300; strong sulphuric acid, washing the part directly after with cold water; and a saturated solution of sulphurous acid. Although any and all of these means will sometimes effect a cure, I am disposed to prefer as most uniformly successful the sulphur and white precipitate ointment. Dr. Gull, I am told, has found the strong sulphuric acid rapidly cure the disease. Dr. Coster of Hanwell Schools employs a solution of two drachms of iodine in one ounce of oil of tar; this solution is to be painted on the part with a firm brush.

Whatever treatment may be adopted, cleanliness is essential. The patches should be well washed from time to time, so as to remove the scales, and with them innumerable sporules and much mycelium. As a detergent a solution of borax will be found useful. The parasiticide ointment should be well rubbed into the part at least twice a day.

It has been proposed to pull out the hairs from the patch; and no doubt the success of the epilation would be marked, if it were possible to perform it. But epilation is impracticable; the hair breaks off just above the point where it emerges from its follicle. In rare instances only can the root of the hair be extracted, and in rarer instances still can the root-sheath be got out with the hair. Blistering the part assists in the removal of the hairs. As the secretion of the hair follicles in strumous children seems particularly favourable to the growth of the trichophyton *tonsurans*, cod-liver oil is useful.

It is satisfactory to know that although *tinea tonsurans* may be very obstinate, it always disappears after a time, and, further, that it never causes even partial baldness.

Tinea favosa or *farus*, though common in Holland and some other parts of the Continent, is a rather rare disease in England. Its ordinary seat is the hairy scalp. Now and then, however, it occupies other parts.

Be it situated on scalp, trunk, or extremities, the disease is primarily seated in the hair follicles, and is characterised by dry brimstone-yellow crusts, each crust being cup-shaped, and having a hair running through its centre. The size of the crust varies from a mere point to half an inch in diameter. The separate crusts coalesce as they increase in size and number, and thus a large, dry, irregularly-pitted crust is formed. The crusts are buried to some depth in the cutis, so that if one be raised from its place, a depression of the cutis is exposed in which it was imbedded. The depressed surface is always redder than healthy skin; but only here and there is the cutis denuded of its epithelial covering. Among the dry crusts are usually a few pustules. These pustules are an accidental complication indicating the coexistence of impetigo.

The crusts of *tinea favosa* have a peculiar fætid odour, and from the impediment

they offer to cleansing the head favour the occurrence of vermin. The pediculi are found chiefly in the fissures of the large crusts. Intolerable itching is often experienced. There is a variety of *tinea favosa* in which the crusts are from the first amorphous, wanting in the cup-shaped character, and less bright in colour.

Microscopic examination.—The pus from the pustules contains the corpuscles characteristic of that fluid. The dry yellow crusts are composed of the mycelium and sporules of the *achorion Schönleini*. The sporules of the *achorion Schönleini* are oval, and much larger than those of the *trichophyton*. The mycelium and the sporules can both be seen readily in the hair which runs through the centre of each dry sulphur-coloured crust.

The steps of the disease are these;—First, there is thickening of the root-sheath of the hair follicle, and accumulation of its secretion about its orifice. So long as there is nothing more than this, we are not able to say that any disease exists; but let the sporules of the *achorion* fall on the prepared soil, and the sulphur coloured crusts of *tinea favosa* are rapidly formed. The plant grows outwards between the layers of epithelium, downwards into the follicle, and, entering the hair near to its root, shoots upwards into its substance.

The *trichophyton tonsurans*, the plant proper to *tinea tonsurans*, grows into the hair follicle; but its presence inflicts no permanent injury on the structures of the follicle. The *achorion Schönleini*, unless it be soon eradicated, destroys the follicle, and permanent baldness is the consequence.

Herpes circinatus bears the same relation to *tinea favosa* that it does to *tinea tonsurans*. The secretion of *herpes circinatus* is as favourable to the growth of the *achorion* as it is to the growth of the *trichophyton*. *Tinea favosa* is, like all the diseases of its class, contagious, but the *achorion* requires a favourable soil for its growth. The disease rarely spreads in the hospital.

The writer had a case of *tinea favosa* for some time under his care in the Hospital for Sick Children: not a child caught it till a case of *herpes circinatus* was admitted into the same ward. On several children rings of *herpes circinatus* soon after appeared; and two of the children thus affected now caught *tinea favosa*, and the crusts of the *tinea favosa* occupied the centre of the patches of *herpes circinatus*.

As these cases are of interest from their bearing on the pathology of the affection, one may be quoted at length.

On the outer aspect of the right arm, just below the elbow, is a pinkish-red patch, slightly elevated, nearly circular, and five-eighths of an inch in diameter. The centre of this patch is occupied by ten or twelve crusts of *tinea favosa*, the largest not more than a line in diameter, the smallest requiring a lens for its detection. The largest are distinctly depressed in the centre, the smallest are merely yellow spots. Through the centre of each crust runs a little hair. A few white scaly-looking points are scattered around the part occupied by the crusts. The circumference of the patch is covered by pretty closely set, flattened vesicles; the majority so small that they might escape observation, unless the part were examined with a lens.

On the right shoulder, the left upper arm, and the left leg, are patches of similar character.

Passing from the circumference to the centre of the patch are—

- 1st. A ring of the vesicle of *herpes circinatus*.
- 2nd. Scales formed by the drying of the vesicles.
- 3rd. Crusts of *tinea favosa*.

Some of the crusts are mere points, the disease being limited to the very orifice of the hair-follicles. There are no pustules; not a trace of suppuration; a sufficient proof that the disease is not pustular at its commencement.

As without the existence of the plant *trichophyton* there could be no such disease as *tinea tonsurans*, so in regard to *tinea favosa*, were there no such plant as the *achorion Schönleini*, there could be no such disease as *tinea favosa*. The soil requires preparation; but all the visible phenomena of the disease—those appearances which we call *tinea favosa*—are the direct consequences of the presence of the plant.

Treatment.—The objects to be kept in view in the treatment are to remove or destroy the plant, and to improve the state of the secretions of the part which is its seat. As the subjects of *tinea favosa* are often strumous, benefit is obtained under such circumstances from the administration of cod-liver oil, syrup of iodide of iron,

calumba, rhubarb, and soda, and other remedies of the same class. But all other means will fail unless the plant be destroyed and removed. For this purpose, parasiticide substances—that is to say, substances destructive of vegetable life—are to be applied, and at the same time so much of the plant as possible removed by mechanical means.

The crusts are to be removed by a bread-and-water poultice, or, better still, by the continuous application of lint dipped in a solution of sulphurous acid. Bichloride of mercury dissolved in water or mixed with lard in the proportion of eight grains to the ounce, and acetate of copper mixed with lard, half a drachm to the ounce, are two of the most powerful parasiticides. A saturated solution of sulphurous acid properly applied is an excellent remedy; a piece of lint dipped in the solution is to be closely and constantly applied to the affected part, and this covered to prevent evaporation by oil-silk, or by a second piece of lint spread pretty thickly with lard. If the disease be on the trunk or extremities, and the general health good, it may be rapidly cured in this manner. The girl whose case is above described was permanently cured in a few days. But if the disease be seated on the hairy scalp, and the plant has entered the hair-follicles, and shot up into the hairs themselves, considerable difficulty is experienced in bringing the parasiticides in contact with the plant, and, as a consequence, epilation is almost essential for permanent cure. If the hairs be pulled out before the hair-follicle is destroyed, no baldness follows. Epilation may appear to be a very painful operation, but if well performed it is not so. Each hair should be grasped with a pair of forceps adapted to the purpose just where it escapes from its follicle, and pulled sharply in the line of the direction of its insertion into the follicle. As the hairs are much less firmly fixed in their follicles than in health, epilation is so much the more easily effected. If the disease be limited in extent, no practical difficulty exists to its cure by epilation; if it occupies the whole or a great part of the scalp, the cure requires much time and great patience. So long as a sporule or a branch of mycelium remains in a hair undestroyed, so long is it certain that the disease will return.

Before epilation, *huile de cade* is by many applied to the part from which the hairs are to be removed. It is said to diminish the sensibility, and loosen the attachment of the hair to its follicle. The old pitch cap was merely a quick mode of epilation, and not so painful as might be supposed. If *herpes circinatus* be present, the extension of the ring of vesicles should be prevented, and on their first appearance the small patches of herpes should be destroyed with nitrate of silver.

Tinea favosa is the disease described by Bateman under the name of *porrigio lupinosa*. The *porrigio favosa* of Willan, Bateman, and Thompson is a species of impetigo. These excellent observers mistook the yellow crusts of *tinea favosa* for dried pustules.

Tinea sycosis, or *mentagra*, as it is often called, is a disease of the beard, moustache, whiskers, and inner surface of the nates, in which a little fungus finds a nidus between the root of the hair and the wall of its follicle. The plant is the *microsporon mentagrophytes*, and it makes its presence known by the inflammation it excites. The inflammation causes thickening and induration of the tissues around the follicle, and suppuration of the follicle itself. As the disease originates in the follicle, a hair may be seen to traverse the centre of each pustule. The pus and epithelium about the orifice of the follicle dry into a thick brownish scab. When the scabs are numerous, and the parts about tuberculated from the swollen and irregular induration around the follicles, the part affected with pus being supposed to have some resemblance to the pulp of the fig, the name *sycosis* has been given to it. Between the scabs are often seen little scaly particles, formed of epithelium. *Sycosis* may be confounded with impetigo; but the induration and swelling of the tissues is trifling in impetigo. Acne of these parts also may be taken for *sycosis*; but in acne the induration is greater than in *sycosis*, and the suppuration less rapid. There is no vegetable parasite in the hair follicles in impetigo, nor in the sebaceous follicles in acne.

Tinea sycosis is often a very obstinate affection.

The *treatment* of this disease is to be conducted on the same principles as those of the other affections of its class. Substances destructive to vegetable life are to be applied to the diseased skin; and as the plant is *in* the hair-follicles, they must be applied in a form fitted to enter the follicles. An ointment of lard and corrosive sublimate, in the proportion of a grain to the drachm, is sometimes very useful. The white precipitate ointment of the London Pharmacopœia may effect a cure. Dr. Thompson recommends strongly an ointment composed of a scruple of iodide of sulphur and an ounce of lard. Warm fomentations and poultices, by removing the scabs and allaying the inflammation, afford much relief to the patient. The condition of the digestive organs must be attended to, and purgatives, tonics, and antacids exhibited as required. A good and generous diet is usually necessary. Epilation is sometimes essential for effecting a cure.

Tinea or *pityriasis versicolor*, or chloasma, is a very common disease. Its most frequent seat is those parts of the neck, upper arms, chest, and abdomen, which are covered by the flannel jacket. The axillæ, however, usually escape. It is curious to note how often the disease is limited exactly to the parts in contact with the flannel. In such cases its occurrence is favoured by want of cleanliness.

Many people are so dirty in habit as to wear the same flannel next their skin for a week, a fortnight, three weeks, and, among the poor, even a month. And it is by no means an uncommon thing for them to wear the same flannel night and day, not once removing it from the moment it is put on till the time it is considered to be desirable to have it washed. The consequence of such habit is an accumulation on the surface of the skin of its secretion and of undetached epithelium, and the consequent formation of a nidus favourable to the growth of the *microsporon furfurans*. This plant finding, then, in the epithelial accumulation saturated with the secretions a fitting soil, spreads under its outer layer in all directions, and by its presence produces the pale yellowish-brown patches characteristic of chloasma. At the margin of the larger patches are numerous detached brownish-coloured circular spots. The spots are scarcely raised above the surface of the skin. Like all the other vegetable parasites, the *microsporon furfurans* exhibits a disposition to spread from the point on which it alights uniformly in all directions. Hence the circular form of the patches. The large irregularly-shaped patches are formed primarily by the coalescence of the smaller. If one of the brownish patches be rubbed, a number of minute scales will be detached, and the cutis underneath will be seen to be somewhat redder than the adjacent skin. The only annoyance the patient experiences is itching of the part on exercise or when heated, and the consciousness of having very unpleasant-looking skin beneath his jacket.

No doubt some persons who are very cleanly in their habits, and some who are as cleanly as their clear-skinned neighbours, suffer from chloasma. One concludes, therefore, that in some instances the secretions of the skin are abnormally favourable to the growth of the fungus.

Phthisical people often have patches of chloasma on their chest or elsewhere. This is the result, partly at least, of want of cleanliness. Persons delicate in the chest, as they call it, are frequently afraid of washing more than face and hands. Again, they usually keep themselves closely wrapped in flannel, and are somewhat too fearful of changing it; and, yet further, sweating, alternating with heat of skin, is common in such cases—conditions favourable to the formation of a good nidus for the *microsporon furfurans*.

Like all the parasitic diseases, chloasma is contagious.

Microscopic examination.—If one of the delicate scales from a patch of chloasma be placed in a little alkaline fluid, and examined with a magnifying power of 250 diameters, it is seen to be formed of epithelial scales studded with the mycelium and spores of the *microsporon furfurans*. If to the scale water only be added, the plant will not be visible. The alkali renders the animal matters transparent, and leaves the plant unchanged. The *microsporon* is seated on the under-surface of the

epithelial scales, no part of the plant projecting beyond the margin of the scale on which it grows.

Treatment.—To cure the patient, his dirty habits must be reformed, supposing him to be of such. He must change his flannel frequently, and never sleep in that which he wears during the day. He must wash daily, not merely his hands, but his whole trunk and extremities, using hot water and strong soap. After washing he must rub the surface well with a flesh-brush, taking care that the latter is itself often cleansed. In addition to these frequent and careful ablutions and frictions, by which a large quantity of the fungus is removed, the patient should bathe the part affected with a parasiticide lotion, composed of twelve grains of bichloride of mercury to four ounces of water. The lotion should be allowed to dry on the part. A saturated solution of sulphurous acid may be applied freely with the same object, viz. to kill the fungus. A lotion of sulphuret of potassium, one drachm to the pint of water, will cure; but then it is offensive. Some consider a course of arsenic essential to the permanent cure; but it is not so. Cod-liver oil may be of service in some cases.

The following appears to me to be the present state of knowledge on the subject, and on the relation between the parasites of the parasitic skin diseases and between herpes circinatus and parasitic diseases.

1. That herpes circinatus may occur without any vegetable parasite being able to be detected on the part.

2. That trichophyton tonsurans is frequently present in the scales of h. circinatus and in the hairs of the part.

3. That if a wet bandage be applied over the skin of a part on which trichophyton tonsurans has been scattered, patches identical with those of herpes circinatus containing the parasite are produced.

4. That microsporon furfurans can be inoculated in the same manner, but then no other disease than chloasma follows.

5. That if achorion Schonleini is inoculated, tinea favosa is produced, but that an herpetic stage resembling h. circinatus precedes the favus stage, and that in some cases the disease aborts at the herpetic stage, no favus crusts being formed.

6. That patches of true herpes circinatus are more liable than other parts of the same person to be inoculated with achorion Schonleini and so to have favus crusts form in their centre.

7. That the lower animals, the cat especially, suffer from tinea tonsurans and tinea favosa, and that man may be inoculated from the lower animals.

8. That the microscopic characters hitherto noted of the various parasitic fungi, while amply sufficient to enable the one plant to be distinguished from the other, are not sufficient to prove their essential non-identity—i.e. to prove that they are not different stages of development of the same fungus.¹

With reference to the nomenclature of these diseases, characterised by the presence of vegetable parasites, it should be remembered that—

Tinea tonsurans was called by Willan and Bateman porrigo scutulata;

Tinea favosa was called porrigo lupinosa;

Chloasma was called pityriasis versicolor; while the

Porrigo favosa of the same authors was a variety of impetigo.

¹ Höbner u. Strabe, *Klin. u. exp. Mittheilung*, Canstatt, J. B., 1864. Starck u. Hallin, *Jena Zeitschrift*, Canstatt, J. B., 1865. Pick, *Untersuchung in der Pfl. Hautkrankheiten*. McCall Anderson, 'On the Identity of the Parasites met with in Favus, Tinea Tonsurans, and Pityriasis Versicolor.' [I should like to express my own opinion that the parasites of the three parasitic diseases, ringworm, favus, and chloasma, are absolutely distinct from one another, and that, allowing the existence of circinate forms of erythema, lichen, and herpes independent of parasitic influence, still in the great majority of these affections a parasite will be found, and that in the great majority of cases therefore they are simply varieties or stages of ringworm or favus.—J. S. B.]

Scabies.—The eruption of scabies is caused by the presence of a minute animal parasite, the *sarcoptes hominis*, in the under layer of the epithelium. The *sarcoptes hominis* has been taken from its burrow, placed on a healthy person, and the disease in that way communicated. It is by the passage of the parasite from one person to another that the disease spreads; hence the hands in the adult, and the buttocks and loins in children too young to walk, are the especial seats of the disease. In children the hands often escape; in adults the parts of the hands where the skin is most delicate are the parts first to suffer, i.e. between the fingers, the bend of the wrist, the root of the thumb, and the inner margin of the hand. Scabies never affects the hairy scalp or the face of the adult, and only rarely the face of the child.

The eruption appears to be produced thus: The animal bores a way through the outer layer of the epidermis, and then for some distance onward, in the softer layer of the epidermis. Immediately adjacent to the point at which the animal passes into the epidermis, a vesicle, papule, or pustule is formed. The *sarcoptes* itself is found at the end of the faint whitish line or burrow leading from the vesicle or papule. The burrow varies from a line to an inch in length. When the disease affects the delicate skin between the fingers or toes, and continues for some time, the cuticle thickens and cracks. These cracks are very characteristic of the disease; the vesicles, papules, and pustules, and the delicate line leading from a few of these, are the only disease of the skin directly resulting from the animal's presence. The blackish points, the linear abrasions, the broader inflamed patches, and the ulcers so common in the young child, are the consequences of injury inflicted on themselves by the patients, in their endeavour to allay the intolerable itching. Hebra has pointed out that when the paralytic are the subjects of itch, none of these severer effects of scabies are observed. The vesicles of scabies are scattered irregularly over the part affected; many of them seem buried somewhat in the skin, so that they may be mistaken for papules. These deep-seated vesicles are never acuminate, and there is little or no redness around them; on the apices of some of the papules a minute vesicle may be detected by the lens; those vesicles, the vascular character of which is more evident, are acuminate, and may or may not have some redness around. The phlyzacious pustules often attain a considerable size.

The superficial acuminate vesicles are best seen between the fingers and toes and at the bend of the wrist, the disease being recent; the cracks in the same situations when the disease has lasted some time; the buried vesicles on the upper extremities, and where the epidermis is naturally rather thick; the burrows of the *sarcoptes* on the sides and anterior aspect of the fingers. It is a matter of some interest, as showing the accidental nature, so to say, of the eruption, to know that some good observers have recorded cases in which there were no vesicles, pustules, or papules, only the burrows, at the extremities of which were found the *sarcoptes*; the itching in these cases was as severe as in those attended with an eruption. In old persons, whose skins are thick and not very sensitive to irritants, the eruption is often trivial and papular in character. The disease is then not infrequently confounded with prurigo. The itching in scabies is very decided and severe, and greatly increased by warmth. The amount of inflammation and ulceration that may accompany the disease when it affects the delicate skin of young infants is likely to lead to a mistake as to its nature. Vesicles and pustules sometimes form under the thick cuticle of the sole of the feet, and are very characteristic of the disease.

Scabies never disappears spontaneously. I have seen cases where the disease has lasted for years, its nature having been misunderstood.

Prurigo and eczema often complicate scabies; urticaria less commonly; and in rare cases blebs form on the irritated parts.

Treatment.—Sulphur is the best remedy for scabies. It cures the disease by killing the *sarcoptes*. In the St. Louis Hospital at Paris, two hours' treatment is considered sufficient for the cure of the disease. The patient, after being well washed with soft soap for half an hour, is strongly rubbed for the same space of time over the whole surface with the sulpho-alkaline ointment of Helmerich, composed of eight parts of lard, two parts of sulphur, and one part of carbonate of potash, and

directly afterwards placed in an alkaline bath. The patient's clothes are fumigated with sulphur.

The objections to this method of treatment are, that eczematous eruptions often follow its employment in persons with a delicate skin, and that the ointment stains the linen. The sulphur ointment of the Pharmacopœia does not cure so rapidly, although it does so quite as certainly as the sulpho-alkaline ointment. The great use of the alkali is to remove the superficial layer of epithelium, and so expose the sarcoptes more completely to the action of the sulphur.

Supposing that, from the position in life of the patient, it is desirable to hide the odour of the sulphur, the best scents for the purpose are the essences of bergamot and of lemons; a little bisulphuret of mercury will conceal the colour of the sulphur.

Devergie recommends, if the odour of the sulphur be highly objectionable, that the patient be placed for an hour, or an hour and a half, daily in a bath containing from two to three drachms of bichloride of mercury. Five or six baths, he says, suffice for the cure. Iodide of potassium may be substituted for the bichloride of mercury, but then more baths are required. Bazin advises, under like circumstances, that the surface be rubbed daily with an ointment composed of powdered chamomile-flowers, lard, and olive oil, in equal parts.

When scabies is present, no matter with what other eruption it is complicated, the scabies is to be first cured, and this although the sulphur cause considerable increase of the complicating affection, *e.g.* eczema.

DISEASES OF THE HAIRS.

Porrijo decalvans is very readily recognised. The roots of the hairs atrophy, till at length, being smaller than their follicles, they fall out. Commencing at a point on the hairy scalp, the disease spreads circularly till a bald patch of some size is formed. Now and then the bald patches are irregular in form; still even then the margin of the patch is usually scalloped, as though the large patch had been formed by the coalescence of several smaller patches. The disease may ultimately involve the whole scalp; nay, occasionally the hairs of the eyebrows and the eyelashes are similarly affected, and fall in like manner from their follicles. There is neither redness, heat, tenderness, nor any eruption on the bald patches; usually, indeed, the bald scalp is something paler than natural.

P. decalvans is common enough in children and young persons. It more rarely affects those of more advanced age. The patches from which the hair has fallen are quite smooth. The patches of *tinea tonsurans* must not be confounded with those of *p. decalvans*. In the latter the surface of the patch is quite smooth—there is local baldness, and that is all; in the former the hairs look as if they had been cut off just above the point at which they emerge from their follicles.

This disease has been called *tinea* in deference to the statements of Bazin and others; the writer has never detected any vegetable growth on or in the hairs about to fall from their follicles. The plant, the *microsporon Audouini*, is said to be found attached to the hairs just above the surface of the scalp. The atrophy of the bulb of the hair is considered to be secondary to the action of the plant.¹ Willan called this disease *porrijo decalvans*. It is called by some *alopecia circumscripta*.

Treatment.—If the patient be pale or weakly, iron and cod-liver oil may be given. Local stimulation is, however, far more important. Tincture of iodine is a convenient stimulant, it may be applied night and morning. A saturated solution of sulphurous acid is very efficacious. It should be applied constantly by means of a piece of linen soaked in the solution, and covered with an oil-skin cap. The linen requires to be wetted many times a day. Sometimes the saturated solution of the acid is too stimulating; and if so, it may be diluted with as much or more water—just so much diluted as that it may produce a little redness of the scalp, but no eruption. If the

¹ There is no sufficient evidence that this disease is parasitic; I have never detected any trace of a parasite. It is not contagious, and, moreover, it runs in families like psoriasis.—J. S. B.

patches be small, tincture of iodine is the best application; when the disease is extensive and spreading rapidly, the head should be shaved, and the sulphurous-acid lotion applied. If less powerful stimulants fail, blisters may be applied. As the hair-follicles are seriously at fault, and new hair has to be formed, a cure cannot be quickly effected. The first sign of improvement is the presence of a little downy hair on the patch. This down is, after a time, replaced by better-formed hair, and this again by still more perfect hair. The baldness is rarely permanent.

Plica polonica (*der Weichselzopf*, Germ.)— This is a disease of the scalp which is endemic in Poland, Livonia, some parts of Russia and Tartary, beyond which countries it is scarcely known.

The real nature of this disease is not yet clearly proved. What is visible to the naked eye is a firm matting together of the hairs, and the presence of a sticky material between them. The matted hair sometimes takes the form of a single long tuft, sometimes of several smaller tufts, and sometimes of an irregular mass, forming a kind of cap. The disease is usually confined to the head; but is sometimes met with on the chin, in the axillæ, and on the pubes. There is pain and great tenderness of the scalp, which bleeds on the slightest touch.

It is doubtful what is the source from which the sticky material between the hairs proceeds. Fuchs believed that it came from the hair-follicles; G. Simon regards it as an abnormal secretion from the surface of the skin, not especially implicating the follicles. When it is examined microscopically, it is found to be made up of epidermis, threads of cotton, silk, and wool, with particles of sand, insects, &c. Sometimes, especially in cases of long standing, cryptogamic vegetation is found amongst it. The older writers described the hairs as thickened, swollen at the roots, and infiltrated with sticky reddish or reddish-white fluid. Later writers have not confirmed these observations. (G. Simon¹ found no change in the hair, either at the root or in the shaft; it was not brittle or infiltrated with any abnormal material. He could not find, as stated by Gunsburg, any vegetation in the hairs themselves.)

On chemical examination, the peculiar matter has been found to consist of extractive matters, with ammoniacal compounds, fats, and fatty acids; with some salts, especially chloride of sodium, sulphate, phosphate, lactate, and acetate of soda; with but little potash, magnesia, iron, and silica. These analyses throw no light on the nature of the disease.

It has been suggested by Hebra that plica polonica is not a distinct disease, but eczema, or other skin affection, much neglected. This theory obtains some plausibility from the circumstance that in Poland there is a popular prejudice that this condition of the scalp is a cure for other maladies. On the other hand, it is not confined to the poor and ignorant, and is met with beyond the limits of Poland. T. H.

LOCAL DISEASES OF THE SKIN.

CORNS.

CORNS in their origin are merely local hypertrophies of the epidermis, situated for the most part on the feet, occasionally upon the hands, and more rarely over the prominences of the elbows or knees.¹ They are produced by intermittent pressure or friction, localised either by the natural prominence of the part affected, or by the peculiarities of the exciting cause.

Thus, on the feet they are produced by the irritation of ill-fitting boots. These, either from being too small, subject the most prominent points on the foot to undue pressure, or more generally, from being misshapen or too large, chafe and irritate the feet in walking. The peculiar distortion of the toes occasioned by short shoes—namely, the extreme contraction of the flexor tendons, the doubling-under of the extremities of the toes, and the dislocation of their phalanges on the dorsal aspect predisposes to the formation of corns. Arising from this cause, they usually occur on the flat ends of the toes which press downwards against the sole of the boot; or on the dorsal surface of one of the phalangeal joints, which, being unnaturally prominent, are thereby exposed to friction against the upper-leather. In a less degree, tight stockings are a cause of corns by crowding the toes and hindering the even spread of the foot in walking. On the hands these growths may occur upon the palms or upon the knuckles; they may be produced by the friction of the tumbler in tailors and sempstresses. In such as play upon the harp and violoncello they are often found on the palmar surface of the finger-ends and thumb; and more rarely the friction of the pen in writing will be sufficient to produce them on the second finger or thumb. Again, the peculiarities of certain manual occupations may excite their growth upon the prominences of the knees or elbows.

From the occurrence of corns in very young children as soon as they begin to walk, and from their prevalence in certain families where both parents are sufferers, it cannot be doubted that a predisposition to their growth may be communicated by hereditary transmission. As has been mentioned above, intermittent and frequently repeated irritation, by friction or pressure of a *certain degree*, is required for the production of a corn. This acts by stimulating the cutis to the formation of an undue amount of epithelium, forming the characteristic thickening of the cuticle. Should the irritation, however, be excessive, either in its degree or its duration, effusion of serum between the cutis and cuticle takes place, and a blister instead of a corn results.

Corns may be broadly classed under the terms *hard* and *soft*. The *hard* may be either flat and horizontally laminated in their structure, or fibrous and vertical in the arrangement of their parts. Again, in various stages of their development corns differ in their connections with surrounding tissues.

If a hard flat corn be examined in its earliest condition, it will be found to consist of a simple thickening of the cuticle, not well defined in extent, in shape somewhat like the flat head of a nail, and composed of epithelial scales, condensed, and having a regular horizontal lamination in their arrangement. By maceration such a corn may be completely separated from the cutis, leaving the subjacent papillæ distinct and well defined, and in no way altered from their normal condition. In its further progress the growth becomes more clearly circumscribed, and, increasing in thickness, produces greater pressure on the parts beneath. In old-established corns,

¹ A case is related of a corn occurring on the tongue at King's College Hospital, under Mr. Hulke's care. *Med. Times and Gazette*, 1861, p. 556.

situated over the phalangeal joints of the toes or some other prominent point of bone, this pressure and continued irritation generally gives rise to the formation of a bursa beneath, though the occurrence of a subjacent bursa is by no means an invariable consequence.

From the examination of corns that have evidently existed many years, and have from time to time been subjected to treatment, it appears that the long-continued pressure and frequent removal of the upper layers of the cuticle may at length lead to complete absorption of the papillary structure of the skin. Such corns may be found based upon the fibrous tissue of the sheaths of the extensor tendons of the toes, all intermediate structures having been absorbed.¹

The progress of corns, the pain they occasion, and their ultimate result, differ with the varying intensity of their exciting cause, and with the different plans of treatment adopted for their cure. Thus, excessive irritation from pressure or other causes may excite inflammation and suppuration in the cellular tissue or bursa which often lies beneath. The matter in these cases generally finds exit by bursting, the thickened epithelium may scale off, and a cure result; or the matter, before bursting externally, may find its way into one of the phalangeal joints, giving rise to a small but troublesome perforation of the articulation. Occasionally the suppuration of a corn, its bursting, and the consequent exposure of the deeper parts, will lead to loss of one of the phalanges by necrosis. Some time since there was in the wards of St. Bartholomew's Hospital a patient who, from a perforating ulcer originating in a corn, had lost by necrosis the first phalanx of the little toe, together with the distal end of the corresponding metatarsal bone.

Treatment, when not followed by cure, may modify the progress of the disease, by exciting in some cases inflammation, ulceration, or sloughing of the part; such effects being for the most part caused by the application of various escharotics. The ordinary practice of chiropodists—namely, that of cutting out the centre of the corn deeply, leaving the circumferential part, and protecting the centre from pressure by properly adapted plasters—often produces a change in the structural arrangement of the growth. Thus, the central hole may become filled up by what is termed a fibrous corn *i.e.* a corn with a vertical arrangement of its epithelium, which ensheathes a few elongated and sensitive papillæ. By maceration the two parts of the corn may easily be separated; the vertical or fibrous portion coming out like a plug, and leaving a clean hole in the surrounding laminated and thickened epithelium. Another effect of frequent cutting is the permanent depression of the centre of the corn considerably below the level of the surrounding skin, and coincidently with this change there is absorption of the cutaneous papillæ.

The common pearly yellow hue of corns is due to simple condensation of the epithelium. Occasionally minute hæmorrhages take place into their substance, either from some unusual irritation of the cutaneous papillæ, or by injury to their extremities by cutting, or in attempts to extract the corn. The centre of the growth may thus acquire a bluish-black tint, popularly supposed to be the root of the corn, and upon the extraction of which the professed corn-cutter specially prides himself.

Fibrous corns.—These might more properly be called warts, since in them the papillary structure of the skin predominates. They consist generally of a few elongated papillæ ensheathed by epithelium, rough on the surface, and more sensitive to pressure than the ordinary corn. They are situated for the most part on the balls of the toes or soles of the foot, rather than on the dorsal aspects of the phalanges; nor have they, in such specimens as the writer has examined, any underlying bursa.

Soft corns are found generally between the toes, and most frequently upon the fourth toe, on one or other of its lateral aspects. They differ from hard corns in being more sensitive and vascular, in the greater rapidity of their growth, and in many of them possessing a pretty distinctly papillary structure. The constant moisture to which they are exposed from their position causes them to be spongy and condyloid in their appearance. Indeed, many that pass under the name of soft corns

¹ Cruveilhier, in tom. iii. p. 927 of his *Pathological Anatomy*, says he has never seen the corn penetrate the subjacent articulation.

upon the feet would, if found in the neighbourhood of the anus, be recognised as condylomata. Not a few have broadly overhanging edges overlying the sound skin around, seemingly the effect of pressure upon their soft and spongy texture. Occasionally a bursa is found beneath them.

These corns are liable to the same accidents as the harder variety; they may inflame, ulcerate, or suppuration may take place in the bursa or subcutaneous tissue beneath them, giving rise generally to a minute central aperture through which a serous fluid oozes for long after the escape of the matter.

In addition to the ordinary and most obvious inconvenience attached to corns—namely, pain, increased by warm or moist weather, and generally most annoying during the spring-time—there are the more serious evils of suppuration and ulceration; the latter being generally a sequence of the former, or in some cases resulting from the indiscreet application of caustic irritants to the corn. In patients with languid or deficient circulation, where, either from want of power in the heart or from disease of the arteries of the limb, the standard of nutrition is too low to resist the ulcerative process, the ulcer may form the starting-point of a slowly progressive gangrene.

Less obviously, though not less certainly connected with these growths, are many cases of lateral curvature of the spine; generally commencing in early life, and taking their origin from a habit of throwing the weight of the body in walking to one side, in order to relieve the pain of a corn on the opposite foot. Among the same class are rare instances of cramped and difficult action of the muscles of the leg and foot, which may excite suspicions of a failure in the nervous energy of the patient, but are really due to the habitually constrained movement of the limb in the attempt to 'favour' a painful corn.

Treatment.—*Hard corns* in their earliest stage will often disappear if the irritation that produced them be removed, and this may generally be traced to the wearing loose, ill-fitting, or patent-leather boots, or it may be simply to the habit of wearing the same boots many days in succession. The application of a drop or two of glacial acetic acid with a camel-hair brush every night will disorganise the cuticle, which may then be picked off with the point of a knife or scissors, or the corn may be rubbed down with a corn-file. The cuticle may be softened for rubbing down by the application of lint steeped in a solution of carbonate of soda, and covered with oiled silk. It is well, after the removal of a corn in the foregoing manner, to protect the part for a time by wearing over it a small patch of soap-plaster spread on wash-leather.

When, from a day of unusual exertion, or from any other cause, a corn becomes inflamed or more than ordinarily painful, it may be covered at night-time with a small patch of wet lint with oiled-silk over it; this both relieves the pain and gives an opportunity in the morning for removing the growth entirely.

The use of nitrate of silver in substance is strongly recommended by some surgeons; it should be applied after the thickened epithelium has been pared down, or, better, picked off; the scale of blackened cuticle which it produces is said to separate in a few days, leaving a smooth and healthy surface, if the corn has not penetrated too deeply. Some discretion must be exercised both as to the condition of the corn (whether inflamed or otherwise) and as to the extent to which this remedy is applied; its injudicious use may produce considerable suffering.

Old-established hard corns are seldom cured, since the patient is unwilling to submit to the restraint and inconvenience of the necessary treatment. Occasionally an illness which confines the sufferer to bed for some time rids him of his corns, or they may disappear in the desquamation following scarlatina.

It is notorious that, as the expression is, those who 'attend to their corns' suffer but little inconvenience from them; while among those who suffer most are such as visit chiropodists at prolonged intervals and purchase for themselves a few weeks of ease at the cost of as many more of suffering. In the treatment of old-established hard corns it may be well first to soften the cuticle by the application of wet lint and oiled silk during some hours; when it is soft and pulpy an incision may be

made with a small sharp knife completely surrounding the centre of the growth, or the same incision may be effected with a succession of snips with the points of a pair of scissors. Having completely circumscribed the corn, its centre may be raised with a fine hook or a pair of forceps, and the included piece may be removed by cutting under its base; each incision being of small extent, or it will cause pain. The margins of the opening left by the removal of the corn may be slightly bevelled off, and a plaster applied made of soft thick buckskin or amadou spread with adhesive material; a hole being cut in the plaster corresponding with the extent of the corn, and the outside margins of the plaster being bevelled off with a sharp knife.

If it be thought sufficient to protect the corn from pressure without previously removing any of its substance, the centre of the growth may (as recommended by Sir B. Brodie) be covered with a piece of linen rag or thin diachylon to prevent it bulging through the hole in the corn-plaster.

Suppuration beneath a corn may be recognised by the intense pain and throbbing of the part; it should be relieved as soon as possible by puncture, the cuticle being previously softened by the application of warm-water dressing. In favourable cases where the circulation in the foot is healthy and vigorous, the opening of an abscess beneath a corn is frequently followed by complete disappearance of the growth; in others, either from general debility or local deficiency in the circulation, this perforation gives rise to a chronic and intractable form of ulcer. Such a sore is best treated by invigorating constitutional remedies; and among these, opium in small doses is generally most effective: locally some stimulating application, such as resin-erate or turpentine ointment, may be used with advantage.

Soft corns seem to owe their existence to the friction of one toe against its neighbour, and their more rapid growth to the warmth and moisture of the locality where they are for the most part found. Unless in a state of inflammation, these corns may generally be cured by the application of the oxide of zinc in powder, or equal parts of this and the pulvis aruginis may be dusted over the growth, and the toe be surrounded with a thin wrapping of cotton wool, after a few applications the corn will either dry up and disappear of itself, or its shrivelled remains may be cut away without pain or inconvenience. The application of the glacial acetic acid will be found very useful in the treatment of soft corns. But, whatever plan be adopted for the cure of the disease, the affected toe should be kept apart from the others by the daily application of cotton-wool.

There are certain corns which, from their situation and cause, require a separate mode of treatment; such are those arising from contraction of the flexor tendons, with doubling under of the ends of the toes and unnatural prominence of the phalangeal joints on their dorsal aspect. The corns from this cause are situated either on the extremity of the toe or on one of the joints on the dorsal surface. In these cases the toes must be straightened, either by strapping the toe or toes to a gutta serena splint placed on the plantar surface, by division of the flexor tendon, or by winding a piece of linen rag or adhesive plaster over the dorsum of the prominent toe and beneath the toes on either side.

Those whose feet are habitually predisposed to corns, or who suffer serious inconvenience either from the number or pain of these growths, should wear boots made from some other material than leather. As a substitute for leather nothing is so good as the invention that rejoices in the classical but ungrammatical name of *pannus corium*. This, from its softness and pliability, is particularly suited to tender and irritable feet. Persons liable to corns should carefully avoid wearing patent-leather boots, as hindering the escape of the cutaneous transpiration.

BUNIONS.

The term 'bunion' is applied to enlarged bursæ situated on any part of the tarsus, metatarsus, or phalanges of the toes; but for the most part placed over the metatarsal joint of either the first or fifth toe, and accompanied with more or less distortion of the subjacent articulation.

To study rightly the exciting cause of this disease, it may be well to revert for a moment to the natural form of the foot uninfluenced by the distortion produced by modern boots and shoes. Perfectly formed feet may be seen in the many shoeless children of the London streets. If such be examined, it will be found that, as regards general conformation, the foot is widely spread towards the toes, that the inner line of the foot and great toe is nearly straight, or, as Professor H. Meyer more accurately expresses it,¹ the central longitudinal axis of the great toe carried backwards passes through the centre of the heel. There should be moreover a considerable interval between the first and second toes along the whole of their contiguous margins; the second and third toes are also separated, though by a narrower interval; nor do the third and fourth toes touch each other when the weight of the body is borne on the foot.

Comparing with this the foot of an adult that has been distorted by the purely conventional shape of modern boots or shoes, we may observe, first, that, from lateral pressure and crowding, all the toes are in close contact with each other, and not infrequently the second or third toe overrides or is doubled under its neighbours, or the little toe is doubled under the fourth toe so that on the dorsal aspect of the foot its root is but just visible. From the same cause the toes all incline towards the middle line of the foot; this distortion particularly affecting the great toe, which, instead of remaining in a right line with its own metatarsal bone, turns obliquely away towards the outer side of the foot; so that if the line of its longitudinal axis be carried backwards, it would fall altogether to the inner side of the heel.

The above-mentioned distortions are easily accounted for by the narrowness of the sole of modern boots, which crushes up the toes into a bunch, and the sloping of the inner side of the boot towards the middle line of the foot thus constantly exercising pressure on the inner side of the great toe and thrusting it over towards the outer side of the foot. Boots, again, very generally by their shortness press on the end of the same toe, pushing it directly backwards, thereby increasing its distortion from the right line, and this, by bearing on the head of the corresponding metatarsal bone, causes the latter to project on the inner side of the foot. In addition to the direct effect produced by the pressure of misshapen boots, the material of which the boot is made may exercise a predisposing influence on the formation of bunion; patent-leather, as it is called, or any material which, like it, completely stops the evaporation of the transpiration from the cutaneous surface, has this effect.

There exists undoubtedly in many persons an hereditary tendency to the formation of bunions, a predisposition in which even the most carefully constructed boots will fail in averting the formation of these cysts.

Though generally situated over the first joint of the great toe, as the part exposed to greatest irritation, yet it is by no means rare to find bunions developed over the prominence of the scaphoid bone, or, again, on the outer side of the foot over the proximal or distal end of the fifth metatarsal bone, and elsewhere on the dorsum of the foot over any prominences where the natural conformation of the part fails to correspond with the artificial and arbitrary shape of the shoe.²

¹ *Protrusio ante Portas*, by H. Meyer, translated by J. S. Craig, Edinburgh.

² Through the kindness of Mr. E. James, of the Melbourne Hospital, we are enabled to quote the following remarks of Dr. George Bennett, of Sydney, in answer to an inquiry by the writer of this article:—

‘Sydney, March 1881.

‘With respect to the distortion of the feet of the natives of this country, I have observed neither in the aborigines of Australia, nor among the natives of the Polynesian Islands I have visited, any of the distortions you allude to as seen on the feet of the civilised races who encase them in shoe-leather. Nor have I seen among the natives corns or bunions.’

In its early formation, a bunion generally attracts attention as a painful and tender spot over one of the metatarso-phalangeal joints previously exposed to pressure and irritation by distortion of the corresponding toe. By-and-by, the part enlarges, indicating an effusion into an already existing bursa,¹ or the formation of an adventitious synovial cyst. This effusion, though the result of inflammation, is generally recognised as designed to protect the subjacent parts from pressure. At this point the disease may cease to make progress; the bursa may remain; and may effect the object to which we have just alluded, occasionally reminding the possessor of its existence by a passing twinge of pain. Far more frequently the bursa, though an efficient protection, reserves to itself the irritation it wards off from the joint beneath; the consequences of this are seen in repeated attacks of pain or inflammation, causing progressive enlargement; or it may be in the formation of callosities or corns on its surface, or in suppuration of the contents of the cyst. The evacuation of the fluid from the interior may be followed by obliteration of the cavity and cure of the disease; but in old people, or in those of languid circulation, it may give rise to a most troublesome form of ulcer.

The perforating ulcer of a bunion has for the most part a pallid indolent appearance, and secretes a pretty abundant sero-purulent discharge. If a probe be introduced, it will generally be found that the size of the external orifice bears no proportion to the cavity of the sore, which latter is relatively very large, and extends some distance beneath the margins of the ulcer; occasionally there is a fistulous passage from the bottom of the sore communicating with the joint beneath.²

Coincidentally with the distortion of the joint, which precedes or accompanies the formation of a bunion over the base of the great toe, there are changes to be observed in the conformation of the articular ends of the bones, in the cartilage, ligaments, and tendons, in connection with the joint. The head of the metatarsal bone enlarges, and is often encircled at its margin by bony deposits; the articular cartilage is almost invariably absorbed, and the bone beneath eburnated. The internal lateral ligament is elongated; and the external so shortened that, if in the dead body an attempt be made to restore the toe to its natural position, this ligament tears. The extensor tendon of the great toe is located to the outer side to a greater or less extent, and in extreme cases the sesamoid bones will be found to have shared in the general displacement, being dislocated with the phalanges of the toes towards the outer side of the foot.

It may be questioned whether these changes in the joint, which are analogous to those occasioned by chronic rheumatic arthritis, are directly the effect of the distortion, or whether they are not rather occasioned by that disease occurring in the joint in question as the '*locus minoris resistentiæ*,' as it has been called. This is the more probable from the known tendency of gout to attack the same joint, and it may be for the same reason.

Treatment.—It is only in the early stage of bunion that treatment will avail for the complete removal of the disease, though palliative measures are practicable at all times.

The tender spot that precedes the formation of a bunion may be advantageously covered by night with wet lint and oiled-silk, while by day a more commodious boot than usual should be worn to free the part from pressure, care being taken that the boot or shoe be wide in the sole, and not sloped off on the inner side towards the median line of the foot. If the part be very tender, it may be covered during the day with soap-plaster spread upon kid or wash-leather.

So soon as a cyst has formed, in addition to the above-mentioned precautions, means should be taken to procure the absorption of its contents, either by the occasional application of strong tincture of iodine, or the continual application of the compound mercurial cerate upon linen rag, the margins of the swelling being protected with some soft plaster. For the cure of bunions when uninfamed, and for such as have much fluid within them, we have found an ointment of biniodide of mercury

¹ For an exhaustive enumeration of natural bursæ, see Schreger, *De Bursis mucosis sub-cut meis*.

² This affection is the '*mal perforant du pied*' of French authors.

most useful; it should be applied occasionally, or at least not so constantly as to blister the skin. The strength we would recommend for this purpose is ten grains of the salt to an ounce of lard.

On the occurrence of inflammation in the sac of a bunion from any cause, water-dressing, or a poultice, will be found the most comfortable application. A careful watch should be kept for any sign of suppuration, since, should it occur, an early and free incision is both requisite for the relief of pain, and is often followed by the complete cure of the disease. It is often the habit of persons suffering from severe bunion and distortion of the toes, to wear boots made to fit accurately their distorted feet. Professor Meyer recommends in such cases the wearing of a shoe so constructed as to tend to restore the toes to their natural position. He says, 'the sole should be cut exactly as if the toe were in its proper position;' questioning, however—and we think with reason—how far such an expedient would be advisable in cases of very extreme distortion of the joints, or prominence of the enlarged bursa.

The difficulty of healing the ulcer resulting from the bursting of a bunion is sometimes very great, especially in old people, or in those whose circulation is languid from other causes. A stimulant local application, such as the resin or turpentine-cerate, will generally be found useful; while the use of opium and stimulants internally, with easily assimilable and nutritious diet, is called for. If, as is generally the case, the ulcer have a small external orifice and deeply undermined and overhanging edges, they should either be destroyed by caustic, or they may be laid open by a crucial incision, or be removed entirely by scissors. Under the most judicious treatment, however, these ulcers, in persons of feeble circulatory powers, or where the arteries of the part are extensively diseased, may form the starting-point for senile gangrene.

Some surgeons have remedied the deformity of the first toe mentioned above by removing the outgrowth from the end of the metatarsal bone. The toe can then be restored to its natural position. Such an 'operation of convenience' should be performed with the strictest antiseptic precautions.

WARTS.

Warts, or verrucae, are collections of overgrown cutaneous papillae, either completely ensheathed by an excessive formation of scaly epithelium, or each papilla of the growth stands beside its fellow, separate, having only its natural cuticular sheath.

Verruca simplex, the most common form of wart, consists of a bundle of hypertrophied papillae, closely adherent, and ensheathed by a thick covering of cuticle; from friction and exposure to the air its surface is generally horny in texture, and is rounded off into a small button-like protuberance. This species of wart is found solitary or in large numbers, chiefly in young persons, and is situated most usually about the hands or fingers, occasionally on the face, and more rarely on other parts of the body.¹

Verruca digitata is a name applied to a less common variety of wart, situated almost invariably on the hairy scalp. On examination, it will be found to be formed of a few cutaneous papillae imperfectly ensheathed by cuticle. This wart is more pedunculated in its attachment to the surface than the foregoing variety; its papillae are long, and often free at their extremities, giving the surface of the growth a ragged appearance. It is found, as stated above, generally on the scalp, and so far as one's own experience extends, only in women after adult age:² such warts, either from their number or from some unfortunate peculiarity in the position of a single growth, may give rise to great pain and inconvenience in brushing or combing the hair.

Subungual warts.—Warts very similar in structure to the foregoing occasionally form beneath or at the side of the finger or toe-nails. Situated here, they are gene-

¹ A case is related of a wart of this kind occurring on the tongue, *Medical Times and Gazette*, 1861, p. 656.

² I have seen them more than once in men, in one instance occurring in considerable numbers.—R. J. G.

rally softer in texture and more rapid in growth than those on the scalp. They originate beneath the nail from the sensitive skin to which the nail is attached, between its free margin and the *real* matrix; and in their further growth they generally crop out either at the free extremity or lateral margin of the nail. Such are apt to be very painful and inconvenient.

Verruca confluens is a term introduced by Mr. Erasmus Wilson to designate a variety of warts found on various parts of the body, chiefly over the neck and upper part of the thorax, or the backs of the hands or arms. The growth in question consists of an aggregation of closely packed but distinct papillæ, often smooth on its surface, and without any evident indication of the isolation of its component papillæ; but on pinching up the skin of the part its surface will break up into minute fissures showing its papillary structure, which bears a resemblance, in M. Rayer's opinion, to coarse plush.

These growths are of uncertain size and shape; they may occur in patches or irregular bands. Either spontaneously, or more generally under some local irritation, they may extend pretty rapidly over the surrounding skin; their advance in any direction being usually preceded by the enlargement, here and there, of outlying and isolated cutaneous papillæ.

Differing in some respects from ordinary warts are those of venereal origin. Such are more vascular in their structure, are often of fleshy consistence, and pedunculated in their attachment to the surface. If those that have existed some time be examined microscopically, their bases will be found to include portions of the structure of the deeper layers of the skin; namely, a dense network of areolar tissue and more thinly scattered elastic fibres: in this particular they resemble old condylomata, and in this they differ from common warts, which consist only of papillæ and their epithelial covering. Venereal warts often have comparatively large blood-vessels entering their under surface. Such warts, from the warmth and moisture of their position, situated (as they usually are) beneath the foreskin or between the labia, grow more rapidly, and attain a larger size than other varieties, propagating themselves abundantly by contact with neighbouring parts.¹

Causes. Though occasionally congenital in their origin, warts are notoriously capricious in their appearance, period of duration, and disappearance. Some individuals exhibit an hereditary tendency to their formation, and not a few are affected with warts corresponding in position to those existing in one of their parents.

Mr. Sedgwick gives an account of a family under his observation, where warts on the hands have been hereditarily limited to the female line for two generations. The mother herself was much troubled with numerous warts on her hands, which appeared in infancy, continued through childhood, and disappeared soon after puberty. She had five children: a boy aged 11, a girl aged 9, a girl aged 7, a boy aged 5, and a girl aged two and a half. The two boys never had a wart; the three girls are all troubled with them—the eldest has thirty warts, the next daughter has twenty-four on the hands. In both, the warts appeared in infancy, and have increased in number since. The youngest child has two warts at present.²

The period of life between infancy and puberty seems particularly that in which warts grow most luxuriantly. *Verruæ* may suddenly appear either singly or in large numbers; such eruptions generally attacking the hands and wrists; they may remain a longer or shorter time, and as rapidly and unaccountably clear off.

Adults but rarely suffer in this way, though we recently observed a very copious eruption of warts over one side of the neck and upper part of the chest in a lady about forty years of age. They were very numerous, and a few weeks had elapsed since she noticed their commencement; they varied greatly in size, some being just visible, while others were as large as swan-shot. More recently a professional friend showed me a large crop of common warts of various sizes, which had appeared without apparent cause upon his own hands, none of them having existed more than four or five weeks.

The irritation produced by certain discharges, especially by such as are of a venereal origin, is a well-known and generally acknowledged cause of one form of

¹ We have seen in a child warts precisely similar in appearance to the venereal, growing from the commissure of the lips, and lying within them when the mouth was closed.

² *Brit. and For. Med.-Chir. Rev.* April 1853.

wart; and no less certain is the occasional effect of soot in the production of the malignant wart of chimney-sweepers.

From the frequent occurrence of distinct warts, or warty thickenings, upon the hands of persons occupied in post-mortem investigations, or in the study of practical anatomy, it is more than probable that the poison of decomposing animal matter, under certain conditions, is capable of exciting the formation of these growths. At all events, one's personal experience, and that of many of our pathologists and demonstrators of anatomy, lends support to this opinion. Cadaveric warts have a somewhat special appearance; they are broad-based and flat, and generally the seat of more or less inflammation. In many cases suppuration occurs beneath such a wart, the pus discharging itself by numerous minute openings upon the surface.

Some warts are undoubtedly contagious, and especially those of venereal origin, and such as occur from other causes about the genital organs; next to these in their aptitude to spread by contact are such as occur in crops about the hands.

It is a popular belief that the blood from a wart is capable of reproducing others when applied to the external surface of the body; and a case has recently appeared in the French journals tending to confirm the popular prejudice. M. Cruveilhier states that M. Banuel showed him a band of warts upon the back of the hand, assuring him that they had sprung up in the line of the stream of blood flowing from one of these growths during its removal.¹ But M. Rayer states that 'he has repeatedly tried to inoculate warts in this manner, but the operation has never succeeded.'² Unintentionally one has several times performed the same experiment, and always with a negative result.³ As one would suppose, such warts as furnish a secretion from their surface manifest most decidedly their contagious character; but that this peculiarity is not confined to such, I may refer to a case related to me by Sir James Paget, where an individual with a small and completely dry wart on the foreskin, which had existed for some years, and who had suffered from no venereal affection within many years, married, and communicated to his wife a most abundant crop of warts, which affected the labia and parts about. She in the meantime suffered from no discharge, either leucorrhœal or gonorrhœal. The original wart in the husband underwent no change either in size or appearance, nor did it furnish any palpable secretion.

Progress.—The capricious and sudden disappearance of warts has given rise to a belief in the efficacy of charms for their removal. But it is rare for any but the common wart that affects the hands of young people to disappear in this way; and this may account for the fact that wart-charms have but little reputation for the cure of these growths when of venereal origin.

The common wart of the external integument may remain for many years, or a lifetime, without materially increasing in size; its growth, however, may be stimulated by some permanent source of local irritation; indeed, warts that in their commencement differ in no recognisable feature from the verruca simplex, may in their subsequent progress assume a character in no way distinguishable from epithelial carcinoma: such are usually situated on the face. For an interesting and detailed account of the structural changes occurring in their degenerations, the reader is referred to a paper by Dr. Collis in the 'Dublin Quarterly Journal' for May 1860.

The production of horns by the excessive growth of warts, with the dessication of their external layers of cuticle, will be considered under the head of 'Horns.'

Treatment.—Warts that are dry in their texture and but scantily supplied with blood, such as the verruca simplex and the sculp-wart, may generally be easily removed by some chemical solvent; perhaps one of the most efficacious and manageable of these is the glacial acetic acid; it also has the advantage of being painless in its action. It may be applied with a camel hair brush to the wart until its texture is pretty thoroughly sodden with the acid, care being taken to prevent the blistering of the skin in the neighbourhood; the application may have to be repeated once or twice. Nitrate of silver in substance is a popular but unsightly remedy. Tincture of the perchloride of iron is generally effectual, but it is better suited for the cure of warts that are moist and secreting. The application of a drop of the strong nitric acid, or

¹ *Anatomie path. générale*, tom. iii. p. 926.

² Rayer, *On Diseases of the Skin*, p. 982.

³ I am acquainted with a gentleman who intentionally performed the same experiment, and with apparent success; a wart forming on the back of the hand where the blood was applied.

acid nitrate of mercury, is exceedingly efficacious, and causes less pain than is generally supposed.

Vascular pedunculated warts of venereal origin may be removed at once by the knife or curved scissors; or if too vascular or bulky for this remedy, the application of some drying powder, such as the oxide of zinc, or equal parts of this and the diacetate of copper, or a mixture of equal parts of powdered savine and diacetate of copper; any of these constantly applied will either remove the growths entirely, or bring them into such a condition that they may be safely removed by the knife. Some discretion must be exercised in applying the knife to large crops of warts of long standing or considerable size, situated upon either the glans penis or internal labia, as troublesome or even dangerous hæmorrhage may occur; of this, examples not infrequently occur in the venereal warts of our hospitals. In my own experience I have been compelled on one occasion to apply the actual cautery to the glans penis to arrest the hæmorrhage caused by the removal of a mass of verrucous growths: the bleeding in this case was most formidable in quantity, and quite uncontrollable by other means used for its suppression. In many cases of bulky pedunculated and vascular warty masses, such as affect the external genitals of women, and more rarely those of men, the *écraseur* of Chassaignac will be found a convenient and safe instrument for removing the disease; or they may readily be cut away by means of the *thermo-cautère*. The warty thickenings that occur on the hands from the contact of post-mortem fluids may be treated by the free application of acid nitrate of mercury,¹ or they will slowly disappear if protected from friction. An ingenious method has been devised by the late Mr. Nesbitt, of Wolverhampton, for the removal of pedunculated warts by the application of an elastic ligature. A thin india-rubber thread, much as may be drawn out from an old brace, or a small elastic ring, is applied to the base of the growth, so as to constrict it pretty tightly, though not painfully. In a few days the wart will generally dry up and fall off.

For the cure of congenital warty growths which affect large portions of the skin, and for those described under the term '*verruca confluens*,' the free application of the strong nitric acid is necessary; or the growth, if small, may be excised with the portion of skin upon which it is based. Occasionally it is advisable, in order to avoid loss of the integument, to shave off the papillæ composing the wart with a sharp knife, and to brush the surface over lightly with nitric acid.

The most effectual and speedy cure of warts is by excision of the growth itself, together with the integument upon which it grows; and this is the safest manner of treatment for rapidly growing or degenerating growths, or any which excite a suspicion of a malignant character.

From the situation of subungual warts upon the fingers or toes it is difficult to apply caustics, or to remove the disease by excision; where this is the case, the papillæ composing the growth may be pulled out separately by means of the forceps—a proceeding easy of execution, and causing but little pain.

HORNS.

Differing but little in their elementary composition from warts, horns, by their different structural arrangement, and by the greater exuberance of their growth, present but little external resemblance to these growths. True horns consist of scaly epithelium, more or less condensed and dessicated, for the most part containing within them a fibrous-looking papillary core derived from the true skin, and consisting of extremely hypertrophied papillæ, each thickly ensheathed and separated from its fellow by a condensed cuticular covering. These are supplied freely at their base with blood-vessels, which penetrate some distance up the centre of each. They form the matrix from which layers of cuticle are continually being formed and pushed onwards.² Such horns may be called '*papillary*.' They are marked

¹ This, however, is a very painful application. In my experience fuming nitric acid, or even sometimes excision, are less painful and more efficacious methods of dealing with them. In some belladonna and glycerine will effect a cure.—R. J. G.

² For a good description of the minute structure of these horns, see a paper on human horns by Mr. A. M. Edwards, *Edin. Med. Journal*, November 1860.

externally by longitudinal lines, are rough and fibrous-looking, and generally taper towards their ends, their free extremity being often finely pointed. As might be supposed from the large growing surface presented by the papillary core, these horns are often very rapid in their growth, and attain to a larger size than any other variety. They grow generally from the free surface of the skin, being immediately connected with it.

Another type upon which horns are formed is where they grow from a vascular matrix, flat, or very slightly projecting beyond the level of the skin, and sending no prolongations into the interior of the horn itself, which in this case is formed entirely of epidermis in various stages of condensation. These horns are generally marked by annular constrictions at pretty regular intervals; they have a tendency to curve or become spiral, and bear, for the most part, a greater resemblance to the horns of the smaller ruminants than the papillary variety.

These horns, moreover, from the more horizontal lamination of their component parts, more readily break off and more easily crack transversely; while the papillary horns, from their fibrous arrangement, split longitudinally at their extremities, but break off with difficulty. Perhaps the best examples of the former description of horn are met with growing from the matrix of the toe-nails, or from the interior of sebaceous cysts, where, indeed, they attain their largest dimensions.¹

There is in the Museum of the Royal College of Surgeons an anomalous specimen of a horn formed of compact bone, ensheathed by a covering of horny matter; the bone within the horn apparently has no continuity of tissue with the skull. The parentage of this growth seems to be uncertain, since it is described in the catalogue as '*supposed to be an excrescence from a human scalp.*' Bony projections from the exterior of the skull, having the external appearance of horns, but being connected with the bones of the skull, are not true horns but exostoses, and are generally of the variety termed '*ivory.*'

From tabulated accounts of cases of horny growths,² it appears that out of 151 cases, 81 occurred in females, and 70 in the opposite sex. From the same tables one may gather the comparative liability of certain regions of the body to these growths. Thus, of 142 cases, 63 grew from the head: 32 from some part of the lower limb: 23 from the trunk, on one or other of its aspects: 16 from the face: and 8 from the glans penis. In addition to these, we may take into consideration horns growing from the toe-nails, which are by no means rare among those old women of the poorer classes who jealously guard their feet from the contact of water.

Origin of horns.—A generally acknowledged and common source of human horns is from the interior of sebaceous cysts, such as frequently affect the hairy scalp. They may arise from the interior of an unruptured cyst, and bursting through the cyst-wall may continue their growth external to it; but far more frequently the horn takes its origin from the secreting surface of a cyst that has either burst spontaneously or been accidentally ruptured. Such may grow with extreme rapidity, the exposure to the external air having the double effect of stimulating the increased secretion of epithelial matter, and of rapidly drying that already formed to a horny consistence.

A growth, differing in its structure in no material particular from the horns of sebaceous origin, is often found growing from the matrix of one of the toe-nails, being most frequently situated on the great toe. They may be found from one to four inches in length, tapering at the point, and often curved spirally like a ram's-horn. In these growths, the layers of epithelium forming the nail, instead of lying, as is natural, parallel to the long axis of the phalanx, lose their horizontal arrangement, and, becoming more vertical, turn upwards as they are pushed forwards from below by the growing matrix.³ The exterior of these horns is dense and partially

¹ For an excellent description of the structure and manner of growth of this variety of horn, the reader is referred to Mr. Erasmus Wilson's work on *Diseases of the Skin*, p. 621.

² Erasmus Wilson's *Diseases of the Skin*, p. 624; where also is a reference to a paper by M. Looze in *Mém. de l'Académie royale de Médecine*, June 1830.

³ A good example of such a growth is seen in St. Bartholomew's Hospital Museum, series xxvii, species 24.

translucent, having the appearance and consistence of horn; the interior is composed of epithelium, less condensed, and easily separable into layers. Cruveilhier considers that the pressure of the bed clothes in old and bed-ridden people gives rise to these growths by irritating the matrix of the nail. The best specimens that I have seen of this form of horn have been among old women who have presented themselves as out-patients, in whom, therefore, this cause could not have been in operation. Moreover, it may be generally observed that these horns turn outwards, lying over the tops of the other toes, their direction being influenced by the shape and dimensions of the shoe.

The papillary horns, as they are called, in their commencement differ but little from some of the dry kinds of wart; indeed, it is more than likely that many of these growths are of warty origin. Mr. Erasmus Wilson denies the possibility of this mode of origin, in opposition to Cruveilhier.

In the College of Surgeons Museum is a specimen 'of a horny growth from a wart on the hand.' It is about three inches or more in length, about an inch in diameter at its base, and has a longitudinally fibrous structure; it is an undoubted horn. I myself removed a small horn, about half an inch in length, attached to the integument of the neck, from a woman in whom I had the opportunity of watching its origin in the form of a small wart.

Horns are occasionally found in connection with epithelial cancer, and generally grow from the thickened and tuberculated skin at the margin of the cancerous ulcer. Cruveilhier cites a case of this kind connected with the lower lip. A patient presented himself at St. Bartholomew's Hospital with a recurrent epithelial cancer of the heel, connected with which was a horny growth in the form of a large flat boss, which on removal proved to be true horn.¹ Analogous to horny formations of this kind are such as are occasionally met with in the keloid disease of cicatrices, and in chimney-sweeps, come 'ed with cancerous warts.

Treatment.—The only efficient treatment for these growths is by complete removal, together with the portion of the skin upon which they are based; or, if springing from the interior of a sebaceous cyst, the whole of the cyst should be dissected out. Such as grow from the matrix of the toe-nails are best removed by a fine saw, if too dense for the knife; the nail being subsequently pared away to its proper shape and dimensions. Any subsequent tendency to exuberant growth from the same part can be checked by the application of the glacial acetic acid, which possesses the property of dissolving epithelial structures.

BOILS.

Furunculus, or boil, is a circumscribed inflammation of the skin and subcutaneous areolar tissue, attended by a local effusion of lymph, and followed by the death of the central portion of the involved tissue; and this, the core, is subsequently expelled through an opening in the cutis, together with the degenerated products of the inflammatory process.

Among minor differences, which are chiefly those of degree, one may distinguish pretty clearly between such boils as are lumpy, definite in extent, and prominent on the surface, and such as are flat and less defined in their outline.

(a) *The ordinary boil.*—The former of these varieties generally commences as a lump beneath the skin; at first perhaps but little sensitive; this as it increases in size seems to irritate the surrounding tissues, producing pain and heat about the parts; at the same time, the external swelling becomes more pointedly conical, and acquires a bright-red blush on the surface. The pain is now more considerable, and is of a piercing, throbbing character, occasionally varied by a distressing sensation of tension and weight at the part affected, the surface of which is now exquisitely sensitive to the slightest external irritation. It is probable, as has been suggested, that the sloughing process is during this time extending through the dense structure of the

¹ A case is related by Mr. Hutchinson in the *Pathological Transactions* for 1857, of a horn growing from the angle of the mouth; the base of this eventually became the seat of a papillary epithelial cancer.

true skin ; since before long a purulent spot appears at the apex of the swelling, and coincidentally the local suffering is considerably diminished. This pustule, or vesicle, after a slight increase in size, bursts, and gives exit to a little sanious pus, and discloses a narrow opening leading straight through the cutis, to a greenish-yellow slough beneath. After a variable interval, the slough becomes loosened, and presents itself at the cutaneous orifice, which appears far too small for its convenient exit ; through this, however, it makes its way—a small shreddy wad of dead tissue, soaked in inflammatory products. The subsequent progress towards recovery is rapid ; the flask-shaped bed of the boil for a day or two discharges some sanious shreddy pus ; then quickly fills up with granulations, and cicatrisation takes place, leaving behind a small, depressed, and slightly-discoloured spot.

Boils are considered by some to be confined to the true skin, and not to affect the subcutaneous tissue ; the core, or slough, is also said to be almost entirely composed of inflammatory products.¹ In this opinion we cannot coincide. The slough, or core, if examined microscopically, will be found to consist of the elastic and fibrous elements of the deeper layers of the true skin, matted together by lymph in various stages of disintegration.

(b) *The flat, more diffuse*, or, as it is termed, the 'blind' boil, generally commences in a small inflamed pimple, surrounded by a red and exquisitely tender areola, ill-defined in its margins. The pain of such a boil is from the first of a throbbing nature, keeping time with the pulsation of the heart, and is greatly increased in severity by any excitement of the circulation, such, for instance, as follows the administration of any diffusible stimulant.

The pimple in the centre of this form of Boil either very slowly pustulates, or, more generally, forms a vesicle containing blood-stained serum ; and on the giving way of the cuticle, this is discharged with a little shreddy sanious pus, and with far less solid slough than separates from a common boil. The blind boil, also, so far as our own observation extends, seems to belong to a more atonic and debilitated state of system than the ordinary lumpy boil. Occasionally boils spontaneously disappear without proceeding to suppuration ; such are generally slow in their formation, and cause but little pain.

For the most part, the progress of a boil is not attended by any constitutional fever, nor is their eruption preceded by any distinctive premonitory symptom ; yet not infrequently individuals who have had much experience of boils in their own persons can anticipate the appearance of each fresh visitor by the occurrence of a certain feeling of general discomfort and chilliness, while in others the eruption is preceded by a transient irritability and querulousness of temper.

Boils may be stated to be in almost every case local manifestations of certain constitutional conditions. It is usual in treating of analogous affections, first to treat of the general causes and symptoms which produce and precede the local malady. But since no distinctive group of general symptoms can be pointed out as indicative of an approaching eruption of boils, we have ventured to reverse the order commonly observed in the systematic description of disease, and shall proceed from the description of the characteristic and constant symptoms of the local malady to the consideration of the less definitely marked conditions of the constitution at large, which precede and apparently occasion the eruption. We adopt this course, hoping thereby to arrive at some rational indications of treatment, not so much for the boil itself, as for the conditions of the system that determine its appearance.

Among the causes of boils, it is generally recognised that certain atmospheric conditions largely influence the predisposition of the population at large to this disorder. Thus, as a matter of certainty, we know them to be more prevalent during the spring and early summer than in the autumn and winter. Again, during certain years boils have prevailed in this country epidemically ; they did so in the years 1851, 1857, and 1858, when their appearance could not be connected with any unusual atmospheric condition of which we have any cognisance. There are, however ;

¹ A clinical lecture by Mr. Syme, *Lancet*, March 8, 1856, p. 269. Rokitsansky makes the same statement, *Path. Anatomy*, vol. iii. p. 85.

certain conditions of the system which exercise a definite influence in the production of boils; such a condition is induced in the majority of patients under the hydropathic treatment, as it is called. Here an alteration in the patient's diet (for the most part in the direction of greater simplicity), the diminution or deprivation of stimulants, copious draughts of water, a greatly increased secretion from the skin and kidneys, will sooner or later almost unfailingly produce a general eruption of boils.

Again, a constitutional condition highly predisposing to boils is induced in those who subject themselves to the training process which prizefighters and athletes undergo, and which is necessary for those who row in races. The general experience of persons in the better classes of society seems to be, that the more out of condition they are when the training process is commenced, and the harder they train (as the expression is), the more liable are they to boils; i.e. the more sudden and the greater the change in their diet and general regimen, the more liable are they to boils.

Here, again, the condition of the blood predisposing to boils is induced by an alteration of the diet both in quantity and quality, by the unusual muscular exercise producing an increase in the urinary and cutaneous secretions, and a rapid metamorphosis of tissue.

The long-continued slow absorption of certain animal poisons by inhalation will in very many people, not thoroughly acclimatised to the atmosphere of dissecting-rooms and pathological theatres, produce what we term the furuncular diathesis. For confirmation of the above statement we would refer, without fear of contradiction, to those whose duties compel them to a daily and prolonged attendance in the atmosphere of a dissecting room; and to such as doubt the relation of cause and effect in this case, we would say, under a strong and painful personal conviction of the truth of the above statement, *experto crede.*

The contact of certain cadaveric emanations and animal secretions is, so far as we are aware, the only local cause which is of itself sufficient to cause boils; such boils, or at least the first of the crop, being situated on the part to which the poison has been applied. It is not uncommon in making a post-mortem examination where the wrists and hands come freely in contact with the fluids of the corpse to feel a peculiarly stinging sensation on the surface; and in a period varying from a few hours to a few days afterwards, one or more boils may in such a case (or where no such sensation has been experienced) appear on the surface of the hand or forearm. These boils generally commence in one of the hair-follicles on the hand or forearm, these being the spots where the poison finds most ready access to the surface of the cutis.

A statement has been made by Mr. Gamgee concerning the influence of certain animal poisons taken in the shape of food in the production of boils.¹ He states that 'the flesh of animals affected with pleuro-pneumonia, when eaten by man, causes boils and carbuncles to an incredible extent.' 'My observations,' says Mr. Gamgee, 'were made in three establishments; one where 1,500 persons were known to be supplied with diseased meat; another where several hundred soldiers were in the same position; and a third where seventy persons fed too often on the flesh of diseased animals.' It would be interesting to know the exact data upon which Mr. Gamgee founds this statement.

It is a matter of experience familiar to many, that mere changes of diet, and especially the more liberal supply of animal food to those accustomed hitherto to a scanty supply, will not infrequently bring about an eruption of boils. We see this exemplified in the case of young persons leaving their homes in the country and coming to the metropolis or elsewhere as domestic servants; such persons, 'servants in their first place,' as they are conventionally termed, are peculiarly liable to boils until they become used to the more liberal scale of diet.

There is a curious but unexplained relation existing between the diabetic diathesis, and that which precedes or accompanies the eruption of boils: on the one hand, these latter are notoriously frequent in persons suffering from diabetes; and, on the other,

¹ 'The Diseases of Animals in relation to Public Health,' *Edinburgh Veterinary Review*, 1863, p. 258.

Prout, Wagner, and others have related cases of transient diabetes occurring during the outbreak of boils.¹ We have examined the urine in several cases, but have failed to confirm these observations. In addition to the probable causes of boils enumerated above, there are many and various circumstances producing a condition of general constitutional debility, during which the patient may be attacked by boils; such as prolonged lactation, measles, scarlatina, and the continued fevers. But the conditions to which we have alluded more at length, furnish examples where the cause and effect bear more evident and constant relation to one another.

From the above considerations it would seem that the appearance of boils cannot always be connected with that condition of the system which passes under the sufficiently indefinite term 'debility;' nor can these eruptions be usually ascribed to mere alterations of quantity in the blood—to conditions of anæmia and plethora; but it seems probable they are more often due to some change in the quality of the circulating fluid.

In the instances cited, we have either the definite introduction of some poison into the system, through the lungs in those employed in dissecting-rooms, through the alimentary canal in those consuming diseased meat; or its application to the external surface of the body, as in the case of the boils of pathologists. Or we may suspect the presence of some abnormal constituent of the blood, as in the boils accompanying diabetes and pyæmia. In other cases we have cited, there is such a change of diet and general regimen as to favour the supposition that the quality of the blood has been altered by a change in the proportionate quantities of its normal constituents.

In persons predisposed to the formation of boils from constitutional causes, the exact seat of the malady is in many cases determined by some local irritation producing transient congestion of some spot on the external surface. Thus those who, by training for rowing, have acquired a predisposition to the disease, will generally suffer on the parts most exposed to local irritation—this part, from the nature of the exercise, being generally the buttock.² In others, the friction of the braces as they pass over the shoulders will localise a boil. Again, the forehead, just where fretted by the rim of the hat, is a favourite spot for their occurrence; and the nape of the neck, where chafed by the shirt-collar, is another. Again, we have seen boils on the back of the first knuckle of the thumb in those employed in cutting out cloth, from the pressure and friction of the scissor-handles.

Among other sources of local irritation, the application of a blister is occasionally followed by a crop of boils on the part: a poultice in some has the same effect, especially if kept long applied: croton-oil liniments in others will localise the disease; and the application of a piece of soap-plaster, as mentioned by Sir T. Watson, has been known to be followed by a succession of boils.

In many cases, however, no local cause can be assigned, and these pests may invade capriciously almost any part of the body; in our own experience we have known two instances of boil on the penis—one on the dorsum, and one on the under surface. Mr. Coulson has met with one on the dorsum of the foot; and they are not infrequent on the backs of the hands and fingers, while the palms of the hands and soles of the feet happily seem altogether exempt from the disease, and the hairy scalp is not often affected, though it is by no means exempt.³

The structure of the integument of the part affected exercises a considerable influence over the character and progress of a boil. In the axille, the perinaum, and parts where the subcutaneous tissue is loose, boils are, for the most part, lumpy, elevated, and clearly circumscribed in their boundary, and the core is earlier and more easily discharged than from those situated over the thick leathery integument of the nape, and the dense skin on the outsides of the forearms and thighs. In these parts

¹ M. Vulpian has recorded a case of temporary diabetes during the progress of a carbuncle. *Gazette hebdomadaire*, 1860, No. 40.

² In rowing the palms of the hands are more exposed to irritation than the buttock; but they are parts of the body exceptionally exempt from this disease.

³ I have once seen boils on the palm of the hand.—R. J. G

the swelling is less prominent, more diffuse, and the slough slowly and more painfully separates from its subcutaneous connections.

In infants and young children boils are infrequent; and if they occur, their ordinary progress is somewhat modified, especially if the child be fat; the death of the cellular tissue is more extensive, and the loss of skin by sloughing greater; the disease in its course and termination more resembles the phlegmon of young children.

The local mischief occasioned by boils is, for the most part, transient, though the cicatrix is often permanent, since the skin, at the central point of the swelling, is not merely perforated by the escape of the core, but suffers loss by sloughing.

Twice only has it fallen to our lot to witness any serious or permanent local injury. In one of these cases, a stricture resulted from a boil situated on the under surface of the penis; in the other, the sloughing during the progress of a boil laid open the sheaths of the flexor tendons of the hand, just above the annular ligament of the wrist. This accident led eventually to destructive suppuration of the wrist-joint.

The effect of boils on the constitution at large cannot but vary with the state of the general health at the time of attack. From the consideration of some of the known causes of boils, one may venture to conclude that their action is in certain states of the blood eliminative, though their frequent occurrence, from the amount of suppuration and discharge accompanying them, and the pain they occasion, may induce or increase a condition of general debility. A more serious, but happily an infrequent, effect of boils is the purulent infection of the blood and the production of pyæmia.

Of this the following will serve as an instance.¹ A gentleman aged 46 who had suffered many times before from boils, was attacked with one on the back of his hand, which, contrary to his usual custom, he allowed a surgeon to open by incision. In a few days he was well enough to go out of doors, but the day following he was attacked by pain in the chest and dyspnoea; this was followed a day or two later by intense pain in the left hip-joint, severe constitutional fever, pain and swelling of both wrist-joints, increase of the dyspnoea, and death three weeks after the opening of the boil. The post-mortem examination disclosed an abscess in the left hip-joint, turbid fluid in both wrist-joints, and numerous pyæmic abscesses scattered throughout the lungs.

Treatment.—In considering the constitutional treatment generally adopted for boils, we shall for convenience separate the rational remedies, as they may be called, from the empirical.

When the cause of the attack is assignable with some degree of certainty, there is a definite indication of the line of treatment most likely to prove successful. Thus, boils resulting from the slow absorption of poisons emanating from decomposing bodies in dissecting-rooms or elsewhere, are best treated by the early administration of a laxative, by procuring a free excretion from the skin by means of the Turkish bath, warm baths, hot-air or vapour baths, or, better still, by muscular exercise in the open air; and by a liberal and mixed supply of nutritious food with stimulants in moderation.² In such a case, if a tonic seems desirable, quinine, with mineral acid or some preparation of bark, will be found most suitable.

The indications for treatment are also definite where boils are occasioned by a sudden change either in the quantity or quality of the food; and in such instances the remedies naturally suggested by the circumstances of the case are for the most part successful. In such it may generally be observed that the diet has consisted chiefly of some one class of food, to the exclusion, either partial or complete, of some other; or that the crop of boils has been preceded by some system of diet and regimen which enforces either a complete abstinence from, or a very restricted use of, alcoholic stimulants. We are here referring particularly to the scale of diet adopted by persons under training, or the hydropathic system.

¹ I am indebted to Mr. Edward Newton for the particulars of this case.

² During the progress of a boil, and before it has burst, stimulants, if given in large quantities, may much increase the pain.

If, in contradistinction to these systems, we observe the effects of a well-selected and sufficiently-varied scale of diet on a number of individuals of various ages and both sexes, the contrast is striking. Mr. Gover, resident medical officer at the Millbank Prison, informs us that he imagines there is scarcely any establishment of equal size in which boils are so infrequent as at that prison. Out of a population of 1,000, they scarcely have a dozen cases in a year. 'I presume,' says Mr. Gover, 'that this is due to the compulsory regularity in the habits of the prisoners, the attention paid to cleanliness, and to the fact that the diet, while not in excess, contains every element in due proportion.'

The condition of the urine often furnishes a satisfactory guide to the plan of treatment most suitable to the case—we mean an alkaline reaction, or one of abnormal acidity. The saccharine condition of urine, which has been found associated with boils by some observers, suggests a dietary theoretically appropriate; in practice, however, its adoption has not been followed by any marked success.

The effects of prolonged lactation, the convalescence from fevers or other exhausting diseases,—all of these conditions present sufficiently appreciable deviations from the standard of health to afford a guide to the treatment of boils resulting from them.

But there still remains a large number of cases in which either no definite cause can be assigned for the attack, or in which, though the cause be recognised, the rational plan of treatment has not proved successful. To such cases the various *empiric remedies* are applicable; and first among these remedies we would rank *yeast*, both on account of our complete ignorance of its action on the animal economy, and from the beneficial and speedy effect it apparently exercises in a certain limited number of cases. It may be taken fasting, a tablespoonful at a time, three times a day; and its use need not be continued longer than a fortnight or three weeks; since its effects, if beneficial, are soon evident.

Quinine, given in the manner recommended by Dr. Jackson of the United States,¹ may be recommended as an empirical though successful remedy. Dr. Jackson's plan is the following: he gives from 'twelve to sixteen grains of the sulphate of quinine, divided into three or four doses, on the first day; and if the peculiar effects of the medicine on the head and ears do not take place, he increases the quantity next day by four grains; and continues to increase the quantity daily by four grains, until there is some evidence that the patient has got as much as he can comfortably bear. On the day after some inconvenience is occasioned by the medicine, the daily quantity is diminished by four grains. If this is borne well, or whatever daily allowance is borne with ease, it is continued for four or five days, and then gradually reduced to two grains in a day.' Dr. Jackson recommends that the quinine should not be entirely given up for three or four weeks, and insists on the necessity of beginning with large doses, so as to make a distinct impression on the system as early as possible.

Acids or alkalis are occasionally administered empirically: that is, when there is no particular indication of their being required; they are in such cases given in large doses and are generally combined with some tonic. [Sulphide of calcium, in doses of gr. $\frac{1}{6}$ frequently repeated, is strongly recommended by Dr. Sydney Ringer in the treatment of boils.—R. J. G.]

Local treatment.—The list of local applications for boils, starting from the time-honoured prescription of the prophet, which is still popular among the poor, includes substances many in number, and very various in their nature and consistence; and, first, of the reputed curative measures—

Boils may be subjected to treatment of an abortive kind, and occasionally so with some success. Whatever remedy be applied with this object in view, the period when it is likely to prove successful is only in the very early stage of the boil's existence, and, so far as our personal experience extends, chiefly in the case of blind boils.

This variety may often be quenched early by the application of nitrate of silver, in the solid stick, to the part of the swelling where the vesicle is about to form: ^a

¹ *Letters to a Young Physician*, Boston, 1855.

drop or two of the strong liquor ammoniæ or liquor potassæ applied to the same part is said to have the same effect; and strong tincture of iodine is recommended for the same purpose. *Incisions* are highly extolled for the abortive treatment of boils by Dr. Jackson, whose work we have quoted above; he recommends the boil, when it is but two or three days old, and but a 'pimple,' to be split with a knife. Mr. Hunter,¹ Mr. Syme,² and many others recommend incisions as limiting the extent of the disease, diminishing the pain, and hastening the cure. All agree in advising that the incision, to be efficacious, should be complete, and employed early. We cannot but think that the employment of incisions for boils is of questionable advantage, as a general plan of treatment; it is seldom that the case is submitted to medical inspection until all hope of an abortive incision is at an end; and we question very much if the advantages claimed by Mr. Syme for his method of local treatment would willingly be purchased by most patients at the cost of the short, though sharp, pang suffered during the division of the boil: there are, however, exceptional cases of severe local pain where an incision may be practised with great relief to the patient's suffering. *Poultices* are applications which give some relief from the pain, and quicken the process of suppuration; at the same time they tend to increase the extent of the boil, and favour the formation of fresh ones in the neighbourhood; if used at all, they should be small. Water-dressing is a better application of the same kind, as being more easily localised.

An application which has great repute as a domestic remedy for boils is the bark of the slippery elm; a piece of this soaked in water forms a soft mucilaginous pulp, which, applied to the part, has much the same effect as a poultice. *Boils*, unless exceptionally painful, or occurring on very inconvenient parts of the body—where their rapid suppuration and speedy recovery is all-important—are best simply protected from external injury by some unirritating form of plaster spread upon leather; soap or lead plaster spread upon kid or chamois leather is an excellent application until the boil has burst, when perhaps the emplastrum or ceratum resinæ are more suitable from their stimulant properties.

CARBUNCLE.

Anthrax or carbuncle is a specific form of local inflammation attacking the subcutaneous tissue and involving the skin, it is attended by effusion of unorganisable lymph, followed by sloughing of the central and deeper parts, and subsequently by destruction of the skin and the separation of the dead tissues in the form of a slough.³

It may be distinguished from a boil by being less clearly defined in its margins, less conical at the centre, for its size less prominent on the surface, and by its manner of perforating the skin by several apertures. At the same time it extends more deeply than a boil, the redness of the skin is of a more livid hue, the pain is more severe, and is accompanied by more constitutional disturbance. Again, unlike boil, it generally occurs singly, and for the most part affects certain localities; it belongs especially to certain periods of life, and its slough differs in its colour, consistence, and attachment to surrounding parts from that of a boil.

Carbuncle shows a decided preference for the male sex: out of 2,818 deaths from carbuncle during fourteen years—namely, from 1847 to 1860 inclusive—taken from the Registrar-General's Reports, but 784 were females.

The disease has notoriously been more prevalent in some years than in others. The deaths registered from this cause gradually increased in number from the year

¹ Hunter, *On the Blood*.

² A clinical lecture by Mr. Syme, *Lancet*, March 8, 1856, p. 269.

³ For a summary of the various opinions concerning the pathology of carbuncle, see a paper by Mr. Ledwich, *Dub. Quar. Journ.* November 1856; also *Dub. Quar. Journ.* February 1864. Mr. Syme, *Lancet*, 1856, vol. i. p. 269, states decidedly that the disease 'is not subcutaneous, but seated in the skin itself.' Having carefully read his description of carbuncle, we must conclude that it differs in some points from the actual phenomena of the disease as it occurs in London.

1847, when they were 77, to 1854, when they reached 300. Since the latter date they have fluctuated between 266 and 193 per annum. In the year 1868 they were 228.¹

These fluctuations in the yearly death-rate have occurred unconnected, so far as we can discover, with any unusual or peculiar atmospheric condition. The deaths have occurred from this disease chiefly among the middle-aged and those more advanced in life, being most frequent between the ages of 45 and 55.²

The common form of carbuncle is rarely met with under the age of twenty; while that variety to which we shall presently allude under the name of malignant or facial carbuncle, generally occurs in persons under thirty years of age. The disease attacks all ranks of life; the upper classes being quite as liable to it, if not more so, than the ill-fed and over-worked poor.

The causes of carbuncle may be generally stated to be purely of constitutional origin, and to depend, when any cause can be assigned, upon conditions of general debility or plethora; while not rarely, individuals are met with, who, without showing any perceptible deviation from the standard of health, exhibit what may be called the carbuncular diathesis—an unfortunate predisposition to disease. Many causes have been assigned as tending to produce carbuncle, while some have considered it of purely local origin.³ It is, however, quite impossible with certainty to assign any particular combinations of anti-hygienic conditions as the predisponents of carbuncle.⁴

Still, from the frequent association of this disease with the gouty diathesis, one is warranted in entertaining an opinion that there is more than an accidental connection between the two, and we believe that in the same way that gout is popularly, but not altogether falsely, divided into the 'rich man's' and the 'poor man's' gout, so might carbuncle be often traced to the effects of opposite hygienic conditions acting on the gouty diathesis.

By some the prevalence of carbuncle during the last few years has been attributed to the more extended use, as an article of food, of the flesh of animals affected with pleuro-pneumonia and splenic apoplexy, diseases which during the same time have been increasing in frequency among stall-fed cattle. On this point Professor Gamgee makes a statement to the effect that he has traced the prevalence of boils and carbuncles to the use of diseased meat in certain establishments where this kind of flesh is largely consumed as food.⁵ Recorded facts, however, are wanting to establish the accuracy of this statement.

Dr. Livingstone, on the same subject, writes: 'When the flesh of animals that have died of pleuro-pneumonia is eaten, it causes a malignant carbuncle; and when this appears over any important organ, it proves rapidly fatal. It is more especially dangerous over the pit of the stomach. The effects of the poison have been experienced by missionaries who have partaken of food not visibly affected by this disease.'

'Many of the natives who persisted in devouring the flesh of animals which had died of this distemper, died in consequence. The virus is destroyed neither by boiling nor roasting.'

On the other hand, cases are recorded where the flesh of animals that, by external

¹ In the Registrar's tables the numbers stand thus: -

Year		Females	Total	Year	Males	Females	Total
1847	50	27	77	1854	218	82	300

³ Address on Surgery by Mr. Pritchard.

⁴ See Report on Carbuncle, *Med. Times and Gaz.* 1854, p. 507.

⁵ The passage is quoted at length in the section on 'Boils.' See also some remarks by the same gentleman, *Lancet*, 1864, vol. i. p. 187.

contact, produce malignant pustule in one individual, was eaten as food by others with impunity.¹ The same author relates an instance of two butchers who were attacked with charbon after having killed and dressed the carcass of a diseased ox, which, as an article of food, proved both wholesome and savoury.² Again, the flesh of sheep affected with carbuncular disease is eaten largely in Scotland, and that with impunity.³

The question of the wholesomeness, or the contrary, of the flesh of diseased animals as an article of food, and its capability to cause carbuncle, is at present *sub judice*; and until those who attribute carbuncular disease to this cause can adduce facts in proof of their assertions, we may fairly state that their case stands 'not proven.'⁴

Seat of carbuncle.—The disease is most usually situated on the back of the trunk or neck, occasionally encroaching on the hairy scalp, on the buttocks, or the extensor surface of the limbs, on the upper or lower lip; its favourite seat being in the dense and fibrous integuments over the posterior median longitudinal line of the body. Carbuncles have been observed on the front of the abdomen and on the sides of the thorax. As a rule, they appear but one at a time, though they may follow one another in succession.

Through the kindness of Mr. Wood of Shrewsbury, we are enabled to quote an exceptional case where the patient at one time suffered from eight: this gentleman had, on a previous occasion, been attacked by carbuncles. He was a free liver, and a large, very large eater, and he eventually died almost covered with carbuncles, having at the same time four on the back, one on the nates, two or three upon the abdomen, and one on the thigh; they were many of them very large.

A carbuncle, as it generally occurs, begins in a painful inflammatory swelling of the integuments, hard to the touch, red in colour, very obtusely conical in shape, and ill-defined in its boundaries: it gradually increases in extent and hardness, diffusing itself through the surrounding cellular tissue as a kind of inflammatory œdema. After a few days the colour becomes darker, the more prominent parts being of a livid red, where the cuticle is generally raised from the cutis by some sanious serum; on the bursting of this vesicle the cutis is seen to be perforated by several small yellow apertures, which give exit to a glutinous purulent fluid. After a time these separate holes, from the death of the intervening skin, merge into one large ragged-looking opening. At the bottom of the cavity thus exposed is seen a slimy, pultaceous slough, extending into the interstices of the surrounding cellular tissue beneath the sound skin, and possessing, as some think, a characteristic factor. During all this time the inflammatory œdema around may have been extending; but on the full exposure of the slough it generally begins to subside, the pain lessens in intensity, suppuration commences, and the dead parts slowly, and as it were reluctantly, separate from their connections, leaving a cavity of very irregular shape, having generally deeply undermined and jagged edges. In the progress towards cure, this is filled-in by granulations up to the level of the skin, and when cicatrised leaves an uneven and often permanently discoloured scar.

The ordinary progress of carbuncle, as above described, may occupy an uncertain interval of time extending from a fortnight to some months; indeed, in a few instances, the vitality of the skin for a long while resists the sloughing progress which takes place in the tissues beneath, giving rise to a chronic carbuncle, where the slough is both slow to form, and when formed is for a time imprisoned by the integuments; such carbuncles, if opened, have the appearance of an abscess with semi-solid contents.

The slough consists of the subcutaneous cellular and fibrous tissues, abundant oil-globules, and the products of the inflammatory process in various stages of disintegration. The depth to which it penetrates is uncertain; but not infrequently on the separation of the dead parts the muscles below are seen completely bared, or even to

¹ Bourgeois, *Pustule maligne*, p. 73.

² *Ibid.* p. 165.

³ *Med. Times and Gaz.* 1863, p. 564; also 1864, vol. i. p. 217.

⁴ We do not of course allude to parasitic diseases.

some extent involved in the sloughing. To such a depth may the disease extend that a carbuncle on the anterior abdominal wall may produce fatal peritonitis.¹

'Death may occur in this disease from exhaustion caused by the sloughing and discharge from the carbuncle; these, however, alone rarely produce sufficient depression of the vital powers to cause death; more frequently, if death occurs in this manner, the fatal exhaustion has been occasioned or aggravated by hæmorrhage from incision of the carbuncle.

When the disease invades to any extent the hairy scalp, death may occur in the same manner and from the same cause so frequently seen in erysipelas of the head; the fatal issue being conventionally attributed in these cases to cerebral effusion, or inflammation of the membranes of the brain.

By far the most frequent and efficient cause of death in carbuncle is pyæmia, as characterised during life by rigors, profuse sweats, and general depression, and occasionally by the formation of external abscesses, and as evidenced after death either by multiple deposits of a fibrino-purulent nature in the liver, lungs, kidneys, and spleen, or by secondary abscesses in the same organs or elsewhere.² During the progress of the carbuncle the urine is thought by many to be saccharine. Cases of this kind have been recorded by Prout, Wagner, and M. Vulpian. But we believe this may be merely a coincidence, as we have been unable to find glycosuria accompanying the attack of carbuncle, nor was this condition of the urine found to exist in thirty-five tabulated cases reported in the 'Medical Times and Gazette' for 1851, p. 569.

Treatment.—Since such conflicting opinions exist on the subject of the local treatment of carbuncle, and as surgeons of eminence and experience take such strong and opposite views on the question, we shall briefly allude to the most common plans of practice. At the same time we venture to suggest that some of the warmest supporters of particular and exclusive methods of treatment seem to pay but little heed to the collateral circumstances of each particular case and the general condition of the patient.

And first, there are those who advocate and practise incisions of various kinds as exercising a direct effect in the limitation of the disease both in its duration and extent.

Secondly, those who repudiate incisions and advocate various kinds of caustics, ascribing to these a similar effect.

Thirdly, there are those who make use of local applications, of a more simple and less heroic kind; and, distrusting the efficacy of both caustics and incisions as means of limiting the extent of the disease or hastening its termination, trust to the constitutional powers of the patient, and the general tendency of local inflammatory diseases to bring about a favourable issue. More recently a plan of local treatment by pressure has been introduced; it is said to limit the extent of the disease, to relieve the pain, and to hasten the separation of the slough.

1. The treatment by incision is adopted in the progressive stages of carbuncle; that is, at any time before the slough has begun to separate, or the inflammation to subside; it is probably the most popular plan of local treatment; and it generally consists in a free crucial division of the carbuncle from the surface towards the deeper parts, extending into the living tissues around and beneath.

An internal or subcutaneous crucial incision has been recommended by Mr. French. In this method a tenotomy knife, with its edge upwards, is introduced into the circumference of the induration; and the whole mass is divided from the deeper parts towards the skin, taking care not to wound the latter, except at the point of puncture; a second subcutaneous division is then made, in the same way, at right angles to the first. When the bleeding has ceased, Mr. French recommends that the surface of the carbuncle be covered with collodion, the slough being allowed to escape through the punctures in the base of the swelling.

¹ *Brit. Med. Journal*, August 8, 1863, p. 152.

² For instances of death by pyæmia from carbuncle, vide *Guy's Hospital Reports*, 1861, p. 406.

Another species of subcutaneous division is employed by some; the parts being split horizontally. By others, the swelling is subcutaneously broken up, and subdivided with a long narrow knife passed in at the side.

2. The method of local treatment by caustic consists in the free application of caustic potash in substance to the centre of the tumour, until the latter is thoroughly disorganised. This plan has been highly recommended by Dr. Physic, and at his suggestion has been extensively adopted in America; while in this country, among others, Mr. Higginbottom and Mr. Pritchard have chiefly advocated the same treatment, which is thus described by the latter gentleman: 'In whatever stage the carbuncle is, the potash is to be applied, and rubbed in freely in the centre until an eschar is fully formed. In the earlier stages, if the skin is still unbroken, it must be used for several minutes, until the death of the central portion is insured: the size of the slough to be made varies with the size of the carbuncle. In general terms, the diameter of the skin to be destroyed should be a fourth, or even a third of the diameter of the indurated and inflamed mass.' This, says Mr. Pritchard, is generally sufficient to stop the progress of the disease. Subsequently, the parts are to be covered with resin, turpentine, or camphor cerate, poultices being avoided. The circumference of the swelling may be covered with collodion, or a strong solution of lunar caustic. Strict cleanliness is to be observed, and the slough allowed to separate spontaneously.

The advantages claimed for this plan of treatment are the following: the avoidance of hæmorrhage; a diminution in the extent and duration of the disease, and thereby a saving of strength to the patient, and a freedom from pyæmia.¹

3. Coincidentally with a widespread and increasing belief in the general tendency of local inflammatory diseases towards spontaneous recovery, a doubt has arisen in many minds of both the efficacy and necessity of such remedial measures as have for their object the cutting short of the progress of a carbuncle. Thus it is that many surgeons, formerly advocates for crucial incisions, are now content to allow the local malady to run its course; while, by a judicious administration of constitutional remedies, they endeavour to husband the strength of the patient, and to place him in the best position to support the tax on his vital powers. This treatment is adopted on the conviction that neither local incisions nor caustics favourably influence the duration or extent of the disease; while, by avoiding incisions, one source of danger—that of exhaustion by hæmorrhage—is altogether excluded; and this is no questionable advantage in old or enfeebled patients. At the same time, another perilous complication, that of pyæmia, is less likely to occur in this plan of treatment than in the case where incisions are employed.

The application of pressure as a curative agent to carbuncles was first advocated, we believe, by Mr. O'Ferrall, who has since embodied his views and experience on this subject in a pamphlet. Strong testimony to the efficacy of this plan of treatment has also been given by Mr. M. H. Collis, in the 'Dublin Quarterly Journal,' Feb. 1864.

The manner of applying pressure is thus described by Mr. O'Ferrall: 'The compression must be firm, and must begin at the periphery of the swelling, and gradually approach its centre. In the early period of the practice, I was accustomed to apply a circular piece of brown soap-plaster, spread on leather or cotton cloth, leaving an opening for the discharge of the pus. This succeeded in many instances; but I found that a firmer support was necessary, in order to give immediate ease to the patient. I therefore covered this piece with straps of plaster, drawn tightly from the neighbouring sound parts, and they by traction exerted a firm degree of compression on the swelling. In some localities, where the tumour is of small size, and traction of the skin is not easily accomplished, I have found a coating of collodion of considerable service, producing, by its contractile properties, a nearly similar result.'²

¹ *Vide* a comparison between the results of treatment by incision and by application of collodion, *Year-Book of Med. and Surg.* 1862, p. 165.

² *Dublin Hospital Gazette*, 1858, 'On the Treatment of Anthrax by Pressure.'

³ *Ibid.*

In reviewing the methods of treatment, we believe that that by incision has the advantage of very generally affording complete relief from pain; that it arrests the further extension of the inflammation is less certain, and we much doubt if the final cure is by it at all expedited.

Among the various kinds of incision for carbuncle, we have not been able to discover that any method possesses an advantage over the time-honoured crucial cuts. The treatment by incision has the disadvantage of causing hæmorrhage, and, it may be, of exposing the patient's life to increased risk from pyæmia; if employed after a carbuncle has ceased to make progress, this treatment may do damage by interfering with the natural process of cure, and by increasing the area of sloughing and suppuration.¹ No universal plan of incising carbuncles, as recommended by Mr. Syme, can be adopted without great danger to many sufferers from the disease. To the young and vigorous, the employment of the knife may bring relief from pain without risk to the general strength; while in the case of those who are debilitated by age or other causes, the questionable local advantages of incision are far outweighed by the certain risk incurred by the constitution at large.

As a local application after the division of a carbuncle, a poultice may be used, or, what is better in many cases, lint steeped in turpentine, spread over the surface; or if there is any tendency to continued hæmorrhage, the lint may be stuffed into the cuts with a probe.

Of the employment of caustics we have no personal experience; it is a plan strongly recommended by competent observers and surgeons of high repute, who have had large opportunities for forming a sound and discriminating judgment on the subject. Of local applications to carbuncle (until the slough begins to separate), the most comfortable to the patient is the common linseed-poultice, or wet lint and oiled silk; the poultice is of itself too relaxing to many skins, and liable to give rise to boils in the neighbourhood; it is rendered more suitable to the particular malady by being smeared over with turpentine and resin cerate. Frequent syringing with warm water, a weak solution of chloride of zinc or of carbolic acid, will quicken the process of separation when the slough has fully formed; and occasionally from large carbuncles considerable masses of slough may be advantageously cut away with scissors.

To the granulating surface after the separation of the slough some application of a stimulant kind is best suited, such as the Peruvian balsam or the cerate of turpentine and resin; while the edges of the cavity may usefully be approximated by careful strapping with plaster.

The constitutional treatment and general management of patients suffering from carbuncle is best conducted on general principles, and on such indications as the age, circumstances, manner of life, and standard of health of the patient afford, and not upon any specific or universal line of treatment directed to the particular disease.

The bowels, if they require attention, may be acted on by some non-irritating aperient; and the diet, if it be necessary to give much nourishment, should be given in an easily assimilable form. It occasionally happens that, starting from the carbuncle, an erysipelatous inflammation of the skin spreads to the parts around; if it is advisable to treat either by the application to the surface of strong collodion, or a paint recommended by Mr. Pritchard of Bristol, consisting of iodide of potassium and iodine, each a scruple to one ounce of collodion;² or the strong caustic solution recommended by Mr. Higginbottom may be advantageously applied.

Facial carbuncle.—Under this name we propose to describe a disease of carbuncular character, which often differs in its progress and consequences so much from the ordinary affection as to require a separate notice. Having most external characteristics in common with carbuncle, in its constitutional effects this disease may be said to bear much the same relation to the latter as does scarlatina maligna to scarlatina simplex. Whether the fatal tendency of facial carbuncle depends upon the structural

¹ Vide *Med. Times and Gaz.* 1854, p. 571, report on Carbuncle.

² *Brit. Med. Journ.* 1863, p. 155.

peculiarities¹ of the part affected or upon the essential nature of the disease, we shall not venture an opinion.

Facial carbuncle has been described, under the name of multiple furuncle of the face, by M. Dumereuil.² It has been alluded to as agminated furuncle of the face by Bourgeois, in his work on malignant pustule. In this country, as we believe, the disease was first described by Mr. Harvey Ludlow, in a paper entitled 'Carbuncular Inflammation of the Lips and other parts of the Face';³ and this is one of the best accounts of the disease that is published.⁴ The cases published by Mr. Ludlow have been claimed by a recent writer on malignant pustule as instances of the latter affection.⁵ 'The cases reported by Mr. Ludlow,' says Dr. Budd, 'are all characteristic examples of malignant pustule.' From this assertion we venture entirely to dissent. In speaking of cases of facial carbuncle, M. Bourgeois, in his work on malignant pustule, states that it is not uncommon to meet with a fatal termination when carbuncle occurs about the mouth or other parts of the face; and that this disease is to be distinguished from malignant pustule by its painfulness, the presence of pus, the character of the swelling, and by other characteristics to which we shall presently allude.

In support of the opinion expressed above, we would direct attention to the following particulars: M. Bourgeois⁶ remarks of malignant pustule that its name is singularly inappropriate, since it conveys an idea of some purulent formation; whereas the secretion of pus is so opposed to the essence of the disease that the recognition of the smallest quantity, in a doubtful case, would show the disease at once to be of some other nature than malignant pustule. At page 301 of the same work, among other diagnostic signs of malignant pustule, the complete absence of pus is enumerated, 'since, if it appear spontaneously, or follow upon pressure, one can say certainly that the disease is not of the nature of charbon.'

On examining the six cases reported by Mr. Ludlow, we find that in five it is stated that pustules appeared on the surface of the part affected; while in the other case, when the diseased parts were incised during life, a thick pultaceous matter is said to have issued from the cut surface, which exhibited punctiform deposits of pus. Out of the five cases that presented external evidences of pus, four were cut into during life; and of these it is distinctly stated that there were isolated infiltrations of pus seen on the cut surface. In all these cases, therefore, pus was found to exist.

Of pain as a symptom of malignant pustule, M. Bourgeois remarks that one important diagnostic sign of the disease is the almost complete absence of pain: and elsewhere he remarks, a singular circumstance is the little pain these enormous swellings produce: while of Mr. Ludlow's cases it is related that one 'suffered intolerable pain,' another 'suffered acutely,' a third had 'sharp throbbing pain,' in another case the pain was 'very severe,' and in two cases the disease is said to have been 'very painful.'

These cases, therefore, differ from malignant pustule by possessing those very symptoms that are stated by Bourgeois to be characteristic of carbuncle of the face. In addition to this, at the time the cases occurred, the question of their being instances of malignant pustule was considered and negatived both by Mr. Ludlow and by others well qualified to form a sound and discriminating judgment.

That carbuncles form on the face, and running the ordinary course of that malady,

¹ The facial vein differs from other external veins in being less flaccid in its walls and more patent in its canal, and communicating at its lower dependent end with the jugular, and by its upper with the sinuses of the brain; thus affording unusual facilities for the escape of morbid material from its canal into the general circulation.

produce no unusual constitutional disturbance, is a matter of common observation ; but that carbuncles, differing in their early stages in no recognisable feature from the above, not infrequently prove fatal, is but too true.

Facial carbuncle generally commences in a small itchy pustule or vesicle upon one of the lips (the upper lip for the most part) ; this vesicle, in a day or two after its rupture, is followed by a firm œdematous swelling of the lip, also of the nose and cheek, producing a hideous deformity. A few pustules, or vesicles, generally soon show themselves about the red edge of the lip, and the swelling extends ; the surrounding induration being perhaps less defined than in carbuncle occurring elsewhere. The pain is most intense, and the colour of the surface generally passes through the shades of bright red, dusky red, and dark plum colour, until it is almost black, particularly about the mucous margins of the lips. Suppuration is slow to occur ; but, if the patient live long enough, pus will form and be discharged together with the disintegrated cellular tissue.

The constitutional symptoms early in the disease indicate great depression of the vital powers, the pulse being generally frequent and feeble, the skin hot, and the tongue soon becoming dry. Too often rapid breathing with pneumonia or pleurisy supervenes, and death occurs from pyæmia ; the purulent infection of the blood either originating in facial phlebitis, as evidenced by the swelling and induration in the course of the veins, and spreading upwards through the orbit to the cavernous sinus, where pus may be formed ; or it may be the general circulation is contaminated through the facial and external jugular veins.¹

The following furnishes a characteristic example of the disease : we are indebted to the kindness of Sir James Paget for its particulars. A young gentleman of moderately strong constitution, when in his usual health, noticed a small pimple on his upper lip ; it gave him no pain at first, but on the second day it enlarged, and became painful ; on the third day he kept his bed, with increasing pain and swelling, and some constitutional fever. He quickly became worse ; and on the fifth day the whole of the left half of the upper lip and part of the adjoining cheek were occupied by a thick hard carbuncular swelling not very distinctly defined in extent. The skin over it was dusky brownish and purplish red, and the rest of the cheek was œdematous, dusky, and hot. He had severe burning pain in the part ; the pulse was 145, full, jarring, and rather hard ; the tongue was dry and brown down the centre ; skin hot and dry ; thirst extreme ; slight headache ; he had had no shivering or sickness, and his appetite was good. The carbuncle was split from the mucous edge of the lip ; there was considerable hæmorrhage, which recurred a short time afterwards so freely as to require pressure to restrain it. He was ordered plenty of wine with nourishing food and bark. After the incision, for the first day the swelling and pain much subsided, the face regained a more natural colour, and the patient passed a good night. On the seventh day, though the parts had lost some of their hardness, yet the general swelling had increased in extent, and pus began to be discharged in flakes from the wound. In his general condition the patient was not worse. On the eighth day the carbuncle had still further suppurated, the general œdema had extended over the eyelids, and there was marked protrusion of the eyeballs and chemosis of the conjunctiva. The pulse had fallen to 104, the skin and the tongue were moist. Next day, the ninth of the disease, the pulse fell to 84, the patient became torpid, and at length nearly unconscious. He ceased to care for his food, his urine passed involuntarily, he became restless, trying to get out of bed ; the eyes were still further protruded. A purge was given, the quantity of stimulant diminished, and a blister applied to the nape. Next day his general condition was rather improved, though the eyeballs protruded more : a slough had separated from the lip, and pus issued sparingly from small holes in its surface ; there was redness and swelling over the right temple. On the eleventh day, he partially recovered his consciousness and power of voluntary micturition, and seemed better generally. On the twelfth he was still better ; a small abscess was opened over the nose ; pustules appeared on the eyelids. The carbuncle was at this time discharging thick pus, was shrinking and softening ; pulse 104, with good power ; food and wine taken readily. Next day the improvement continued in all respects. On the fourteenth day he again became dull and heavy, his pulse rose to 148, his urine was retained, a swelling appeared on the parotid ; meantime the carbuncle was healing, and the swelling of the face was diminishing. During the next two days he became worse ; a pustular eruption appeared about his abdomen and thighs, and two abscesses on his forehead ; and he sank on the sixteenth day ; the carbuncle being nearly healed, the swelling on the face having almost disappeared, and the protrusion of the eyeballs having diminished in extent. During the last few days of his illness there had been noticed some fulness of the veins about the left eyelid, and a feeling of induration about the lower part of the facial veins.

¹ Vide *Transactions of the Clinical Society*, 1870, 'On Malignant Carbuncle of the Face,' by T. Smith.

The cause of death in this case, as in others of which we possess the histories, appears to have been pyæmia, as evidenced, in the case quoted, by the secondary abscesses which formed, and perhaps by the pustular eruption, which, occurring as it did coincidently with an aggravation in the constitutional symptoms, probably indicated a purulent infection of the blood.

From the local symptoms alone, we know of no circumstance that will enable us to determine with certainty in cases of facial carbuncle whether the disease will be of the benign form or otherwise. Early suppuration, moderate pain, and a distinctly limited area of inflammatory cedema, are favourable signs; while the opposite conditions portend, but by no means infallibly indicate, an unfavourable issue to the case. The constitutional symptoms are often the first warning of the serious nature of the disease, and they are generally from the very first of an asthenic type; yet it not infrequently happens that nothing to excite anxiety occurs either in the constitutional or local symptoms until the access of well-marked pyæmic rigors.

Treatment.—In the treatment of facial carbuncle topical remedies seem to have even less effect upon the disease than when employed elsewhere; and incisions, if they exercise (as we believe they do) but little beneficial effect when used for carbuncle in other parts of the body, exercise still less when employed on the face. The indications for general treatment are best found in the constitution and condition of the patient: nutritious food and an abundant supply of stimulants being generally required. Sir James Paget has had good success from the employment of quinine in this disease in very large doses; sufficient, that is, to produce the characteristic symptoms of cinchonism.

MALIGNANT PUSTULE OR 'CHARBON.

The following description of this disease is chiefly taken from M. Bourgeois' work entitled '*La Pustule maligne et Edeeme malin*' (Paris, 1861). For an exhaustive list of the various Continental authorities on this subject, we would refer the reader to an excellent pamphlet on the occurrence of malignant pustule in England, by Dr. William Budd, who has collected a number of interesting cases to establish the existence, and even to some degree the prevalence, of malignant pustule in our own country.

Certain herbivorous mammalia—namely, oxen, sheep, and goats; horses, donkeys, rabbits, hares, and it may be others, are liable to an internal disease, or type of disease, to which various names have been applied. As a class, these affections are termed '*charbonneux*' by the French. The particular disease, as it occurs in the ox and sheep, is termed in this country '*the blood*,' '*joint-murrain*,' '*black quarter*,' or the '*quarter evil*.' The French synonyms for the same are '*quartier*,' '*charbon*,' and '*sang-de-rate*' in the case of sheep; while in the ox the disease is termed '*le sang*,' or '*maladie de sang*.' In Germany the same disease is termed '*milzbrand*.'

Malignant pustule or charbon in man is derived from the poison generated by this disease in animals. The disease can be communicated to man by direct contact with the hair, the hoofs, the horns, the hide, the bones, the flesh, or the blood of the diseased animal; and in this way butchers, farriers, shepherds, and curriers usually acquire the disease: while straw or other litter, hurdles, splinters of wood, stones, articles of clothing, may act as media for the communication of the disease to man. Flies and other insects that have been in contact with the carcasses of diseased animals may also transmit the disease.¹ The use of the flesh and milk of diseased animals is a more doubtful medium of infection; indeed, so many are the instances of a negative kind, where flesh that has caused malignant pustule by simple contact has been taken as food with impunity, that M. Bourgeois hesitates to include this as a means of infection.

Similarly, it is doubtful if the disease can be communicated by contact from man to man, or from man back to animals; such experiments having been at present always followed by a negative result. Nor is it probable that the disease can be

¹ Instances of nearly all the above-mentioned modes of contagion are given in M. Bourgeois' work.

communicated to man in the way of infection; we mean simply by atmospheric influences, and without actual contact with the poison.

The disease almost always attacks some exposed part of the body, and is therefore most common on the face and hands. This is as one would expect, from the local origin of the malady.

For some time after its onset, malignant pustule is a purely local affection, and during this stage it is within control; and if the proper treatment be adopted, it can almost certainly be arrested, and the constitutional effects of the malady be averted.

The following is the usual course of the disease: from one to three days after the application of the virus to the surface of the body, there appears on the part a small red spot like a flea-bite, which is sometimes preceded, and is always accompanied by a smart itching. After twelve or fifteen hours, a small vesicle appears on this spot about the size of a pin's head, containing a little brownish-red or yellow serum, on the rupture of which the itching generally ceases, and the skin beneath is seen to be dry and of a yellowish-brown or black colour. This discoloured spot indicates death of a thin layer of the true skin, which soon extends through its whole thickness.

In less than twenty-four hours a fresh crop of vesicles appears, distended with brownish-yellow serum; they are situated in an irregular circle around the eschar of the skin. At this time the eschar is depressed, dry, of a brownish-yellow or black colour, and but little painful on pressure. After twenty-four or forty-eight hours, the parts beneath swell, harden, and form a solid lump, which is pretty well defined in extent, and can be raised with the finger from the surrounding tissues ('bouton'): this swelling is occasionally absent. The mortification now extends up to, and even beneath, the circle of vesicles. As these are destroyed by the extension of the mortification, fresh ones form on the parts around; while the skin about, which at first was pale, reddens and finally becomes of a livid red colour. As the swelling increases, œdema comes on in the surrounding integument, which is ill-defined in its borders, gradually fading away into the healthy tissue. This swelling is but little painful, the temperature is but slightly raised, and it gradually extends itself, while bullæ form over the dead tissue towards the centre of the swelling. The central slough enlarges, but not to any great extent or depth; it is now extremely hard, while the surrounding swelling and œdema may become enormous. A curious fact, says M. Bourgeois, is the little pain that these large swellings cause; and that when they become painful it may be looked upon as a hopeful sign that a reactionary process has commenced. If the disease be situated upon the trunk or extremities, inflamed and indurated lymphatics are often seen stretching away from the swelling to the neighbouring glands. Such is the usual course of a malignant pustule: at first a red spot, then a vesicle, then a solid and circumscribed swelling beneath ('tumeur charbonneuse') surrounded by a diffused and softish œdema, a dry leathery central eschar, and a secondary formation of vesicles or bullæ.

The more characteristic signs as distinguishing this disease from others may be stated, to be a remarkable freedom from severe pain, the little increase in the temperature of the parts, the dryness of the slough, the *entire absence of pus* in all stages of the malady, and the fact that the destruction of the tissues proceeds from the skin towards the deeper tissue, and not, as in carbuncle, by a central sloughing of the subcutaneous parts, followed by death of the skin.

Malignant pustule generally runs its course either to a favourable or fatal issue in a period varying from four to nine days. One must not suppose, says M. Bourgeois, that all malignant pustules follow this succession of changes exactly as described above. In some cases the eschar is not larger than a lentil, and occupies but a part of the thickness of the integument, the surrounding œdema hardly exceeds the 'tumeur charbonneuse' in extent; which latter may even not exist, and these differences are consistent with the most favourable or fatal issue. Still, for the most part, the more extensive the local affection, the more is there to be apprehended as regards the issue of the case.

Constitutional symptoms.—These may early show themselves; often soon after the appearance of the first vesicle, the patient being seized with rigors, headache, and

symptoms of general depression. At other times the symptoms come on a few days later, most commonly showing themselves between two and three days after the appearance of the circumscribed swelling ('bouton') at the base of the eschar; very soon the tongue becomes coated with a white fur; the pulse is full, frequent, and soft; the bowels constipated; the appetite is lost. These symptoms are generally followed by bilious vomiting, depression, faintings, difficulty of breathing, loss of sleep, a coldness of the external surface, a failure of the pulse, cold sweats, and the patient generally dies in a condition much resembling that of collapse from cholera; delirium is rare. Usually before death the local swelling ceases to increase; indeed, in some few cases, may recede, while the colour of its surface becomes more livid and it loses its temperature.

Post-mortem appearances.—The decomposition of the body is very rapid. The serous cavities generally contain a small quantity of darkish serum; the blood is found fluid and dark-coloured; small ecchymoses are often found on the mucous membrane of the stomach and small intestines, the spleen is engorged with blood and softened; the liver and other parenchymatous viscera are more or less congested with dark-coloured blood.

The posterior lobes of the lungs are much loaded with blood, and the bronchial mucus is blood stained.

The heart and brain show the same tendency to early softening and passive congestions; the local slough, if examined, is found to consist of dry stultified layers, dark brown or black in colour, like old leather in consistence, and creaking when cut with a knife.

Prognosis.—Of the various circumstances influencing the prognosis, M. Bourgeois enumerates—1, the age; 2, the seat of the affection; 3, the constitution of the patient, and 4, the local character of the disease, and its duration before treatment is adopted. 1, the younger the patient, the better is the prospect of recovery; 2, the head and neck are the most dangerous seats of malignant pustule, 3, as in other diseases, the amount of constitutional resistance the patient can oppose to the malady largely influences his chance of recovery; 4, it is a highly favourable circumstance if the patient is seen when the disease is still local, and before the symptoms of general blood-poisoning have shown themselves; and the prospect of recovery is less bright the longer the time that has elapsed since the onset of the malady, and the greater the severity of the constitutional symptoms. A favourable local sign is the existence of a bright-red flush over the part, and any considerable increase in the normal temperature, also the distinct limitation of the local induration may be looked upon as a circumstance of favourable augury.

Treatment. Since this malady in its first onset, and for an uncertain period afterwards, is merely a local affection it is for a time within the control of local remedies; these being any of the more active forms of potential cautery and the hot iron. M. Bourgeois agrees with others in recommending, as the most efficient and easily-applied form of caustic, the solid hydrate of potash, which the former gentleman uses by rubbing the solid stick of potash into and around the eschar and its surrounding vesicles, until it is thoroughly destroyed and the healthy tissues are reached; the semi-fluid detritus is then to be wiped away, and the dead parts allowed to separate by ulceration.

In cases where the disease has made great progress before being subjected to treatment, and the tissues are penetrated to some depth, M. Bourgeois recommends that a layer from the surface of the eschar be raised and removed with a knife, and the potash be then applied. In any case where the local slough extends after the application of the caustic, the latter must be reapplied as soon as the non-arrest of the local disease becomes evident.

The constitutional remedies in this disease are such as the general symptoms of the case would suggest, the indication being to avoid all measures likely to exhaust the patient, and to administer stimulants and nourishing food in an easily assimilable form.

Occasionally malignant pustule assumes another external appearance, to which

M. Bourgeois gives the name of malignant œdema.¹ It differs from malignant pustule only in its external manifestation; in all more essential features the diseases are identical. It is generally met with about the eyelids and face. The prominent feature of this form of the disease is a softish, ill-defined, indolent-looking œdema of a pallid colour, rapidly increasing; the subsequent formation of vesicles is less regular, and the appearance of a characteristic central eschar may be absent, as also may be the central induration.

Since the writing of the original article, this disease has been the subject of careful investigation, and the literature of the subject is now very extensive. It is now known to depend upon the presence in the blood and other parts of the body of a large bacillus whose characters are well marked and unmistakable. A disease affecting woolsorters, and known as 'woolsorters' disease,' has been traced to the same cause. It would be out of place in this work to enter at all upon the natural history of the affection; those who are desirous of studying it are referred to the following publications:—'*Recherches expérimentales sur la maladie charbonneuse*,' par H. Toussaint, of Toulouse; the article on Anthrax by Böllinger, in '*Ziemssen's Encyclopædia of the Practice of Medicine*,' translation by D. Albert H. Buck, vol. iii.; the Brown Lectures, by Dr. W. S. Greenfield, delivered at the University of London, and published in the '*Lancet*,' 1880, 1881; and to the most important researches of M. Pasteur, a brief account of which will be found in his address at the recent meeting of the International Medical Congress of 1881. At the same time little or nothing need be added to the account of the local symptoms, except to say that in some examples of the disease the buttons may be absent, while a diffuse local œdema is found. An interesting communication by Mr. Davies Colley is to be found in the *Medico-Chirurgical Transactions* for 1881. He points out that while the disease is very uncommon in most parts of London, a considerable number of cases are brought to Guy's Hospital which have originated in the leather warehouses of that locality. The Guy's Hospital surgeons are strong advocates of early and free excision of the affected part. It is perhaps also wise to mention glanders in connection with anthrax as a disease that might possibly be confused with it; an account of this disorder will be found in the essay on ANIMAL POISONS.

CHILBLAIN.

This term is applied to certain characteristic local inflammations of the integument of an asthenic type, subject to regularly recurring attacks of congestion. They appear in persons predisposed to the affection under circumstances of sudden variations in the external temperature.

A predisposition to this affection often prevails in certain families; it exists most frequently in the young of both sexes, and in adult females more often than in men. This liability to chilblains generally passes off as manhood comes on, and is but rarely met with in men over forty years of age, though in women it may continue throughout life.

The predisposition to chilblains is often connected with a certain slowness or feebleness of the general circulation, as evidenced by cold feet and hands, and occasional lividity of the finger-ends and lips during winter-time. Their appearance is generally ascribed, and often with truth, to the too sudden warming of a part when thoroughly chilled down by previous exposure to cold. But a change of weather, or of residence to a colder neighbourhood, a sudden thaw after snow or prolonged frost, or the appearance of an east wind, is sufficient to occasion them in many persons. In some individuals, if the hands or feet are chilled down, from any cause, below a certain standard, notwithstanding all precautions to the contrary, it is impossible to restore the temperature without producing one or more chilblains.

There are three kinds, or rather degrees, of chilblains: 1st, where there is simple congestion, generally attended by great itching, alternating with periods of extreme

¹ Bourgeois, p. 105.

tenderness to external pressure ; 2nd, where vesication occurs ; and 3rd, where death of the subjacent skin or areolar tissue takes place.

The same chilblain may pass through all these phases in the above-named order ; but more frequently we find that in the same individual chilblains run a pretty constant course. In some they do not vesicate or break ; in others they vesicate easily, and on breaking show superficial excoriations ; in others, after breaking, the subjacent integument is found ulcerated or more completely devitalised. Again, some persons suffer from chilblains which itch but little, but show themselves as red and intensely sensitive swellings of the integuments. From the appearance of a chilblain in its early stage but little information is to be gained as to its eventual result. Most persons, however, know too well what course their own chilblains will pursue from repeated experience.

The local symptoms and appearance of chilblains are too familiar to require a special description, and we therefore pass them by to allude to a peculiarity belonging to this affection, which, we believe, has not previously attracted notice. The peculiarity to which we wish to draw attention is that regular and periodical exacerbations occur in the local symptoms so long as the chilblain is in progress.

Almost all chilblains are subject to a diurnal attack of congestion, which occurs during the afternoon or towards evening, when the affected part, by a feeling of increased heat and a pricking sensation, shows signs of an increased afflux of blood ; this is soon followed by intense itching, then by swelling, with relief to the irritation ; and lastly succeeds a condition of soreness, aching, and extreme sensibility to pressure, which continues throughout the night, and is peculiarly appreciable next morning, when the sufferer puts on his shoes or boots.

The exact hour of the daily attack of congestion, as well as its severity, may, within certain limits, be influenced by external circumstances. Thus the attack may be hastened by anything which stimulates either the local or general circulation of the body, such as the exposure of the parts affected to the warmth of a fire or a heated room. The constitutional effect of the midday meal in children, and the evening dinner in adults, is generally sufficient to determine the period of attack ; children for the most part suffering in the afternoon, adults in the evening, during or after dinner : conversely the opposite effects may be observed where external circumstances are unfavourable to the advent of the attack, which latter may be postponed until after the sufferer has retired to rest. In many young persons at boarding-schools the extremities are cold throughout the day ; and it is not until the child is in bed that the general temperature is restored to its natural standard. The severity of each daily exacerbation generally bears a direct relation to the degree of cold to which the patient has been previously exposed ; and the colder the chilblains are in the morning, the more will they itch in the afternoon.

We have occasionally met with persons whose chilblains are subject to two attacks of congestion daily : the first occurring late in the afternoon ; the second at night-time, when the parts are warm in bed. In some few persons chilblains do not itch at all—they tingle and burn during the daily attack, and at other times are swollen and extremely tender.

During the onset of the diurnal exacerbation the general circulation is quickened, and the temperature of the affected part is considerably raised, being often ten degrees or more above that of the part before the attack set in, and from one to six degrees above the neighbouring surface of the healthy skin.

Chilblains generally appear on those parts of the body where the circulation is most liable to be affected by changes in the external temperature. In the same individuals, however, the part of the body attacked every winter is little liable to vary. Some suffer on the hands alone ; others on the feet only ; while others may be attacked on both hands and feet ; or, again, the lobes of the ears may be the seat of chilblain, or even the end of the nose. [I have seen chilblains extending under the nails.—R. J. G.]

Of the local causes of this affection those are most efficient that hinder the free circulation in a part, and thereby allow external cold to exercise its most depressing

effects ; such are tight gloves, elastic bracelets and garters, tight shoes, sitting long in cold rooms with the feet pendent, and other circumstances of a like kind.

Treatment.—Though in some persons no precautionary measures will prevent the occurrence of chilblains, nor will any remedy remove them, yet even in these individuals both their number and their severity may be favourably influenced by appropriate treatment ; while in other persons the attack may be either altogether avoided, or if it occur, the chilblains may be cured.

Of general measures either to prevent or mitigate the severity of an attack, the most efficacious are such as promote a vigorous state of the general circulation. In matters of diet, the addition of a glass or two of wine to the daily food, or a morning draught of warm milk with rum, will often prove of service ; while if medicine be required, small stimulant doses of opium with quinine may be advantageously given. In persons liable to chilblains, and especially in young people, additional under-clothing should be worn during cold weather ; and, if possible, an even temperature should be maintained within doors by fires in the sleeping-rooms—for among time-honoured conventionalities, none, in the case of young persons, is more conducive to chilblains than the great inequality that generally exists between the temperature of the sleeping and sitting rooms during winter-time.

The circulation and temperature in the extremities are best maintained by warm and particularly by roomy coverings for both feet and hands. For the hands, loose gloves lined with chamois-leather are best ; and for the feet, large boots or shoes, and wash-leather or woollen socks. Tight gloves and shoes, tightly-laced boots and garters, and elastic bracelets, should be particularly avoided.

As long as chilblains remain unbroken, and if the external surface is not too sensitive to pressure, various stimulating embrocations may be beneficially employed ; such as Wardrop's liniment ; a mixture of two parts of tincture of cantharides with six of soap-liniment ; camphorated spirit ; equal parts of turpentine and copaiba ; or tincture of iodine and soap-liniment. When the external surface is very tender, a good local application is formed by a mixture of two ounces of collodion, six drachms of Venice turpentine, and three drachms of castor-oil, or tender chilblains, that do not itch, may be covered over by an adhesive plaster spread upon kid or chamois leather.

To relieve the itching, if it be excessive and unbearable, some resort to the expedient of rubbing the part with snow, or plunging the feet into cold water ; while others find relief by putting the parts into hot water with a small quantity of mustard-flour in it.

It may happen that the daily attack of irritation occurs at some hour of the day most inconvenient to the sufferer ; perhaps interfering with his enjoyment when in society, or altogether deterring him from both business and pleasure during a certain period of the afternoon or evening. In such cases much discomfort may be avoided by artificially inducing the daily attack at an earlier and more convenient hour, and this may be done by keeping the feet for a short time in mustard and warm water. Vesicated chilblains may be protected by a coating of collodion and castor-oil varnish. For ulcers or sloughs resulting from chilblains, poultices smeared with turpentine, or resin cerate, or Peruvian balsam, may be applied until the slough separates, when the sore may be dressed with any of the above-named applications upon lint.

DISEASES OF THE NAILS.

Onychia maligna is a term applied to a specific form of ulceration commencing about the matrix of the finger-nails. The disease is almost confined to children under ten years of age, and is by no means of frequent occurrence. Among more than seven thousand surgical out-patients under twelve years of age, I have found the disease in nine instances only, and these cases occurred between the ages of one year and seven.

Onychia usually has its origin in a pinch or a crush of the finger-end, such as

may either bruise the matrix or loosen the attachments of the nail. Soon after the injury, the finger-ends swell, and fluid is effused beneath the nail; which latter loses its natural colour, and becomes thin and flattened at the end, or more rarely curled up laterally. As it grows, it turns upwards from its normal attachment, and exposes beneath it an exceedingly foul and painful ulcer, having a peculiar and characteristic fœtor; while the finger-end becomes greatly enlarged and bulbous-looking, its integuments being hardened, shining, and of a livid red colour.

The disease seems little prone to spontaneous recovery; but may continue its progress until the last joint of the finger be lost, or the phalanx necrosed by extension of the ulceration.

The treatment consists, first, in the evulsion of the nail, if it be loose, displaced, or discoloured; subsequently the ulcerated surface may be dressed with black wash, or a lotion formed of one or two drachms of the liquor potassæ arsenitis to an ounce of water. The arsenical application appears to exercise some specific effect on onychia, and rarely fails. [The application of iodoform in powder, and a subsequent dressing with a saturated solution of boracic acid, will be found of great service.—R. J. G.] If these fail, a healthy action may be induced by the application of fuming nitric acid. Such constitutional remedies as seem suitable to each case may at the same time be employed; and among these chlorate of potash, with bark, appears to be of use in many cases. Amputation has been occasionally practised as a cure for this disease, and a mercurial course has been recommended. The former is an unnecessary mutilation, and the latter is not required in the form of the disease described above.

There is a form of onychia having its origin in constitutional syphilis. It usually attacks the toe-nails, and is often associated with ulcerative fissures between the toes; ‘rhagades digitorum’ as they were formerly termed. In this form of the disease the ulceration is generally less extensive, the surrounding swelling is not so considerable, and the nail is less seriously implicated; while the history of the patient, or the concurrence of some other symptom of syphilis, furnishes evidence of the nature of the disease. Syphilitic onychia may be treated locally by the black or yellow wash; it being, of course, of primary importance to adopt appropriate anti-syphilitic measures.

Psoriasis may attack the nails, either those of the fingers or toes; and it is often, though not always, local evidence of constitutional syphilis. In this affection the central part of the nail becomes thickened, rough, and scabrous, and unnaturally convex; the free edge is often split, the cuticular fringe at the bottom of the nail is ragged and retracted, leaving a deep fissure between the nail and the skin of the finger. The whole nail, in an extreme case, resembles in miniature the outside of the concave shell of an oyster. The affection is chronic in its nature, and exceedingly difficult to cure. The nails are liable to some of the vegetable parasitic affections of the skin, such as that of *favus*; Dr. Hilton Fagge has recently discovered in the nails of individuals suffering from ringworm, spores, resembling those of *Tinea tonsurans*.¹

In syphilitic psoriasis the administration of small doses of mercury continued over a long period is liable to prove beneficial; and in cases of non-syphilitic origin the most hopeful constitutional treatment is that by arsenic in combination with some tonic. The appearance of the nails may be much improved by smoothing them down with glass or fine sand-paper; or the roughness may for a time be removed by friction with dilute acetic acid; and at night-time the skin at the margins of the nails may be dressed with a mixture of white precipitate and tar-ointment.

In-grown toe-nail, as the affection is usually termed, occurs, we believe, invariably on the outer side of the nail of the great toe. It is caused either by overcrowding the toes and thereby thrusting the soft parts over the margin of the nail, or by the toe-nail being cut away too deeply at the outer angle, allowing the soft parts to encroach on the proper limits of the nail; which latter, so soon as it again grows up from

¹ *Pathological Society's Transactions*, vol. xxi. p. 407.

LOCAL DISEASES OF THE SKIN.

below, imbeds itself in the overlapping integument. The continued pressure causes considerable pain and inconvenience in walking, and if unrelieved soon gives rise to a fungous growth of very sensitive granulations, which may cover the entire nail.

In the treatment of this affection it is of primary importance to secure a roomy shoe for the foot. If the disease has been but a short time in progress, and has not produced any considerable mass of overhanging integument or fungous granulations, the pressure of the nail on the soft parts may be relieved by carefully packing the cleft or groove on the affected side of the nail oiled cotton-wool in small pieces with the flat end of a probe or the edge of a penknife. This may be effected without causing any pain. The quantity of wool introduced may be gradually increased at each application, until the soft parts are raised and pushed aside, so as to expose the free edge of the nail, beneath which the wool should be inserted until the natural state of the parts is restored; when the nail should be allowed to grow up, so as to form a right angle at the outer corner. If there is much inflammation of the parts, the toe may be kept wrapped in water-dressing during the above-described treatment; while the overhanging integument may be assisted to regain its natural relation to the nail by a strip of adhesive plaster applied to it, and drawn round beneath the toe, so as to exercise some traction on the part.

Another method of relieving the flesh from pressure in more severe cases is by scraping the in-grown side of the nail very thin with glass or the edge of a knife; or the free edge of the nail may be notched, and a longitudinal division be made down to the matrix, by cutting with a knife from the surface. This will allow the partially detached strip, as it grows, gradually to overlap the body of the nail, and thus free the soft parts from pressure.

If other methods of cure fail, it is well to remove the nail by means of a central incision extending well up the back of the matrix, each half is then to be evulsed with a strong pair of forceps. It is sometimes an additional safeguard against a return of the trouble to remove the overhanging integument with the knife.

When, from neglect of remedial measures, the nail has penetrated deeply into the flesh, and there is either considerable ulceration or fungous granulations, the most successful treatment is to remove at once the offending portion of the nail. This may be done rapidly and almost painlessly, with the help of ether spray, by thrusting a strong pair of scissors beneath the nail, from its free edge down to the matrix, and tearing out the outer strip of nail with strong forceps. The same proceeding can be effected more gradually and with but little pain by those skilled in the practice, by dividing the nail with a knife from the surface towards the matrix, and then slowly separating the semi-detached portion from its deep connections.

The exuberant granulations which often form in this disease can be disposed of by dusting with the oxide of zinc, or by a lotion formed of the tincture of the sesquichloride of iron, or they may be destroyed with sulphate of copper or lunar caustic. Removal of the overhanging mass with a knife, though effectual, somewhat prolongs the healing. It has been recommended to treat this affection by the introduction of a thin strip of sheet-lead beneath the margin of the nail. The lead should be bent so as to pass round beneath the toe towards the inner side of the foot. This plan is somewhat difficult to carry out, on account of the pain it is liable to occasion.
